**Introduction**

Adult epithelial tissues depend on the presence of self-renewing stem cells for their long-term homeostasis. Signals from the immediate stem cell microenvironment, or niche, promote stem cell self-renewal, prevent differentiation, and control stem cell proliferation to produce the specialized daughter cells required for tissue homeostasis. Emerging data support the idea that niches are adapted for specific stem cell needs. Classical niches consist of differentiated cells that directly contact stem cells and direct their self-renewal and behavior (Morrison and Spradling, 2008). In contrast, other niches appear to lack a stable cellular component. Instead, stem cells generate some or all components necessary for their self-renewal and maintenance (O’Reilly et al., 2008; Sato et al., 2009). The *Drosophila* ovary houses both types of niche in a structure called a germarium. Germline stem cells (GSCs) adhere directly to postmitotic cells called terminal filament and cap cells (apical cells), which are located at the apical tip of the germarium (Fig. 1 A; Xie and Spradling, 2000). This adhesion-based mechanism promotes GSC retention in the niche and concomitantly maintains stem cell fate.

In contrast, follicle stem cells (FSCs) lack a permanent cellular niche, instead relying on transient cell–cell and cell–matrix adhesion to maintain their position (Song and Xie, 2002; Nystul and Spradling, 2007; O’Reilly et al., 2008). FSCs themselves produce the essential local niche component, Laminin A, which activates integrins on the FSC surface, thus promoting FSC anchoring and proliferation (O’Reilly et al., 2008). In addition, secreted signals produced by apical cells (Forbes et al., 1996a,b; Song and Xie, 2003; Kirilly et al., 2005) stimulate proliferation through canonical receptors expressed on the FSC surface, which is located 3–5 cell diameters to the posterior (Fig. 1 A; Margolis and Spradling, 1995).

In one well-characterized example, Hedgehog (Hh) is expressed and secreted by apical cells (Forbes et al., 1996a), and FSCs express its receptor, Patched (Ptc), and effector proteins Smoothened (Smo) and Cubitus Interruptus (Ci; the fly homologue of Gli; Forbes et al., 1996a,b; Zhang and Kalderon, 2000, 2001). Current genetic data support a model in which apical cell-derived Hh interacts with Ptc expressed by FSCs, relieving Ptc-mediated inhibition of Smo and activating Ci-mediated target gene expression. FSC proliferation rates are affected by mutation of *hh*, *ptc*, or *smo* (Forbes et al., 1996a; Zhang and Kalderon, 2001), which indicates an important role for this pathway in FSC proliferation control.

**Drosophila** Boi limits Hedgehog levels to suppress follicle stem cell proliferation

The recent identification of additional Hh receptors (Lum et al., 2003a; Okada et al., 2006; Tenzen et al., 2006; Yao et al., 2006; Williams et al., 2010; Yan et al., 2010) suggests that regulation of the FSC Hh response may be more complex. Ihog and its close homologue Boi bind Hh with high affinity (Yao et al., 2006; McLellan et al., 2008) and are good candidate proteins for Hh regulation in the germarium. Ihog and Boi function redundantly, acting as coreceptors for Ptc to promote cell-autonomous Hh responses (Yan et al., 2010; Zheng et al., 2010). The murine homologues of Ihog/Boi, called Cdo and Boc, also have been shown to act in Hh receiving cells to enhance signaling (Okada et al., 2006; Tenzen et al., 2006; Zhang et al., 2006). Although these experiments strongly indicate positive functions for Ihog/Boi and Cdo/Boc in Hh signaling during development, these receptors can limit Hh diffusion and negatively affect expression of Hh pathway reporters in some tissues (Tenzen et al., 2006; Yan et al., 2010). The dual function of Ihog/Boi in Hh regulation and the need for precise

Figure 1. boi controls FSC proliferation. (A) Schematic of early oogenesis. GSCs (gray) and ESCs (light blue) contact a cellular niche composed of terminal filament and cap cells (“apical cells,” green). FSCs (red) reside 3–5 cell diameters posterior to apical cells. These stem cells generate daughter cells that coordinate to produce follicles (egg chambers) composed of a 16-cell germline cyst (gray) surrounded by a single follicular epithelial layer (yellow). Egg chambers develop over 7 d to produce mature eggs. (B–D) Germaria in which germ cells (blue, anti-Vasa) and differentiating follicle cells (red, anti-Fas3) are labeled. Stalks between the germarium and the first budded egg chamber average 9 cells in wild type (WT; B) and 18 cells in boi/ mutants (C). Cell numbers for WT (B), and boi/ (C and D) are indicated (brackets). Stalks with excess follicle cells are observed at later stages [b, arrow]. (D) boi mutants exhibit defects in cyst packaging (indicated by side-by-side cysts in a single plane [white arrow] or two cysts surrounded by a single epithelium [green arrow], and polarization defects (round cells, changes in Fas3 staining; arrowheads). (E) Mean cell number in the first stalk for each genotype is shown. *, significant differences relative to WT (P < 0.00000006). (F) Mean numbers of dividing FSCs (PH3+) per germarium are shown. *, significant differences relative to WT (P < 0.002). Error bars represent SEM.

### Results and discussion

Flies bearing homozygous or trans-heterozygous mutations in two loss-of-function boi mutant alleles exhibited excess follicle cells that accumulated between developing egg chambers (Figs. 1 and S1). Although stalks of follicle cells between egg chambers in wild-type flies contained nine follicle cells on average, boi mutant stalks had twice as many cells (Fig. 1, B–E). Additional defects associated with excessive follicle cell production, including improper egg chamber packaging, delayed differentiation, and follicle cell polarity defects were also observed (Fig. 1 D). boi mutant FSCs proliferated more frequently than wild-type FSCs (Fig. 1 F and Table I), which suggests that the increased numbers of follicle cells result, at least in part, from increased FSC proliferation in boi mutants. The number of dividing pre-follicle cells derived from boi mutant FSCs was also higher than wild type (Fig. S1), perhaps because of the inability of mutant cells to differentiate properly (Forbes et al., 1996a; Zhang and Kalderon, 2000; Bai and Montell, 2002). Although previous studies have shown that Boi and its close relative Ihog both function in wing imaginal disc and embryonic development (Yao et al., 2006; Zheng et al., 2010; Yan et al., 2010), Ihog does not appear to play a role in the control of FSC proliferation, as loss-of-function mutants exhibited wild-type FSC proliferation.

### Table 1: Quantification of FSC and follicle cell proliferation

| Genotype                          | Scoring average (SEM)* | P-value versus w^{1118}, 109-30, or babGal4 wild-type control* | P-value versus boi^{109-30}, or boi^{109-30}/babGal4 mutant controls* |
|-----------------------------------|------------------------|---------------------------------------------------------------|---------------------------------------------------------------|
|                                   | Follicle cell number per germarium | Number of dividing follicle cells per germarium | Number of dividing FSCs per germarium | Follicle cell number per germarium | Number of dividing follicle cells per germarium | Number of dividing FSCs per germarium |
| W^{1118}                          | 38.5 (2.1)             | 0.55 (0.1)                                                     | 0.03 (0.02)                                                     | NA                              | NA                              | NA                              |

*Between 25 and 150 germaria from 7-d-old female flies were scored per genotype for each condition. Mean numbers are shown with SEM.

* A two-sample Student’s t test was used for all statistical analysis. Significant differences were achieved at P ≤ 0.05.

* Statistical analysis for the number of dividing FSC per germarium compared to wild-type or boi mutant controls are shown in bold.
and follicle production (Fig. 1, E and F; and Table I). Moreover, the penetrance and severity of boi mutant defects were not affected by reducing ihog levels (boi; ihog/+; Fig. 1, E and F; Fig. S1; and Table I). These results suggest that boi plays a critical, nonredundant role in FSC proliferation control.

Boi is a known Hh receptor (Yao et al., 2006; McLellan et al., 2008), which suggests that direct Hh binding might contribute to Boi’s role in suppressing FSC proliferation. Recent work in developing wing imaginal discs suggests that Boi functions as a coreceptor for Ptc, both stabilizing Ptc localization to the cell surface and promoting Hh pathway activation through Hh binding (Zheng et al., 2010). If a similar mechanism regulates FSC proliferation, Boi should be coexpressed together with Ptc in FSCs and be required cell autonomously within FSCs. Although low levels of Ptc were observed in most cells of the germarium including FSCs (Fig. 2 A; Forbes et al., 1996b), Boi localized predominantly to the surface of apical cells (Fig. 2, B and C). Moreover, reducing endogenous boi levels in apical cells by cell-specific boi RNAi expression (boiRNAi/+; babGal4/) led to follicle cell accumulation and FSC proliferation defects similar to those seen in boi homozygous mutants (Fig. 2, D–G; Fig. S2; and Table I). In contrast, expression of boi RNAi in FSCs and their progeny (boiRNAi/109-30 Gal4) had no effect on follicle cell production or FSC proliferation (Fig. 2, F and G; and Table I). These data suggest that Boi functions in apical cells to suppress FSC proliferation rather than cell autonomously within FSCs.

In wild-type germaria, Hh accumulates on the surface of the apical cells where it is produced rather than in the FSC niche (Fig. 3 A; Forbes et al., 1996a). Moreover, ectopic Hh expression strongly promotes FSC proliferation (Forbes et al., 1996a,b) which suggests that Hh release from apical cells may be a limiting event for FSC proliferation control. If this is the case, then Boi binding to Hh in apical cells may control Hh levels available to FSCs. Consistent with this model, a dramatic redistribution of Hh from apical cells to the extracellular space of the local FSC niche occurred in the absence of boi, without changes in Hh transcriptional activation (Fig. 3 B and Fig. S3). Expression of wild-type Boi in apical cells rescued both Hh localization and the boi mutant FSC hyperproliferation phenotypes (boi; UAS-boi/+; babGal4/+; Fig. 3, C, F, and G; and Table I). In contrast, a mutant form of Boi lacking the Hh-binding domain
Figure 3. Boi sequesters Hh on the surface of apical cells. (A and B) Wild-type (WT; A) or boi<sup>e</sup> mutant (B) germaria showing Boi (green) and Hh (red) expression in apical cells (brackets). Redistributed Hh is indicated (B, arrows). (C) Rescue of Hh (red) and Boi (green) localization by wild-type boi expression in apical cells (bracket, boi<sup>e</sup>; UAS-boi/+; babGal4/+). Nuclei are labeled (Draq5, blue). (D) Boi<sup>FN1</sup> (green) lacks the Hh-binding domain and fails to rescue Hh (red) localization (brackets, boi<sup>e</sup>; UAS-boi<sup>FN1</sup>+/+; babGal4/+). Hh accumulates near FSCs (arrows) as in boi mutants. (E) Ihog expression (boi<sup>e</sup>; ihog<sup>EP</sup>+/+; babGal4/) rescues Hh localization (red). Germ cells are labeled (anti-Vasa, blue). (F) Mean cell number in the first stalk for each genotype is shown. *, significant differences relative to control (babGal4/+; P < 0.00002). **, significant differences relative to boi<sup>e</sup>; babGal4+/+ (P < 0.00002). (E) Brackets indicate apical cells. (F) Mean cell number in the first stalk for each genotype is shown. *, significant differences relative to bab-Gal4/+ or bab-Gal4/+; boi; 109-30-Gal4/++; P < 0.004). **, significant differences relative to bab-Gal4/+; bab-Gal4/+; P < 0.0000002). (G) Expression of Boi 109-30/+, bab-Gal4/++; Hh also may act as a short-range morphogen in the ovary. Ptc and Smo are expressed in most cells of the germarium including FSCs, but were excluded from Boi-expressing apical cells (Figs. 4 E and S3). This suggests that Boi suppresses Hh signaling in cells lacking expression of its downstream effectors. Consistent with this idea, boi mutant defects were rescued by a form of Boi that lacks the Ptc-binding domain (boi(+); UAS-boi(ΔP)2+/+; bab-Gal4/+; Fig. 4, F and G; Yao et al., 2006; McLellan et al., 2008), demonstrating that Boi-mediated suppression of FSC proliferation is Ptc independent. Finally, ectopic expression of Boi in FSCs and their progeny (boi(ΔP)2+/+; 109-30 Gal4/+), the Hh target cells in this system, led to the accumulation of 1.5-fold excess follicle cells between stalks (Fig. 4 F). Thus, Hh signaling was enhanced in cells coexpressing Boi and Smo/Ci, which is consistent with observations in other fly tissues (Yao et al., 2006; Yan et al., 2010; Zheng et al., 2010). Together, these observations support the idea that the role of Boi in Hh signaling depends on the presence or absence of Hh pathway effectors in Boi-expressing cells.

Here we demonstrate that the primary function of Boi in FSC proliferation control is to limit the access of Hh ligand to FSCs. Similar nonautonomous inhibition of Sonic Hedgehog (Shh) signaling has been observed upon overexpression of the Boi/Hh homologues Cdo or Boc in the developing chick neural tube (Tenzen et al., 2006), which suggests that Hh sequestration may be a conserved function for Boi family members. However, roles for Boi or its homologues in nonautonomous control of stem cell factors have not been demonstrated previously. The requirement for precise control of Hh levels for proliferation control in prostate and neural stem cells (Lai et al., 2003; Machold et al., 2003; Karhadkar et al., 2004) suggests the possibility that this mechanism may be conserved in those tissues.

Although classical niches are composed of differentiated cells that provide all information necessary to direct stem cell fate (Xie and Spradling, 2000), FSCs rely on factors, including Hh, produced in cells residing at a distance from their immediate niche (Forbes et al., 1996a; Zhang and Kalderon, 2000; Zhang and Kalderon, 2001; Song and Xie, 2003; Kirilly et al., 2005). The benefit of this architecture for egg production is unclear. In other tissues, complex mechanisms control Hh transcription, secretion, cleavage, time of exposure, and range of diffusion in order to concentrate Hh signal on the appropriate receiving cells (Dahmann and Basler, 2000; Varjosalo and Taipale, 2008). In some cases, such as during neural tube development in mammals, the fate of several neural cells is determined by their position along a Shh concentration gradient (Ingham and Placecek, 2006). In other cases, long-range Hh diffusion is blocked by strong expression of Ptc in cells close to the signal source, promoting short-range, high-level Hh stimulation (Chen and Struhl, 1996).

For FSC regulation, Hh likely acts as a long-range signal that diffuses in a gradient from the apical cells where it is produced (Forbes et al., 1996a,b; Zhang and Kalderon, 2000, 2001). Perhaps an unidentified component of the FSC niche helps concentrate the ligand at the FSC surface, promoting proliferation. Hh accumulation in the extracellular space near FSCs in boi mutants (Fig. 3) supports this idea. Moreover, the FSC-autonomous requirement for ptc, smo, and Ci is consistent with direct, long-range stimulation of proliferation by Hh (Forbes et al., 1996a,b; Zhang and Kalderon, 2000, 2001).

Hh also may act as a short-range morphogen in the ovary. Ptc and Smo are expressed in most cells of the germarium,
including GSCs and escort stem cells (ESCs) lying immediately adjacent to apical cells (Fig. 4; Forbes et al., 1996a,b). ptc-lacZ and Ci-lacZ reporters are strongly activated in ESCs and their progeny (Forbes et al., 1996b; Vied and Kalderon, 2009). Moreover, Hh expression in apical cells apparently coordinates FSC and GSC cell division via an undefined mechanism (King et al., 2001). Perhaps Boi binds Hh within apical cells to increase its local concentration for short-range action, in a manner similar to that observed for the Decapentaplegic (Dpp) receptor Dally in GSC proliferation control (Guo and Wang, 2009; Hayashi et al., 2009). In this case, Hh might activate downstream signaling in ESCs, initiating a signaling relay system that affects GSC and FSC proliferation indirectly. Further work is needed to determine whether long-range, short-range, or both signaling mechanisms regulate stem cell proliferation in the ovary.

The role of nonadjacent growth factor producing cells in limiting stem cell proliferation signals may be a general mechanism in epithelial tissues. In the murine hair follicle and intestine, where stem cells can be identified in situ, underlying mesenchymal cells produce factors that are critical for stem cell self-renewal and function (Rendl et al., 2005; Schmidt-Ullrich and Paus, 2005; Kosinski et al., 2007; Li et al., 2007; McLaren et al., 2009). Transcriptional analysis indicates that these same cells express receptors that can limit the release or range of the growth factor signals they produce (Rendl et al., 2005; Kosinski et al., 2007; Li et al., 2007). Although current data support critical functions for the growth factors in stem cell maintenance (Blanpain et al., 2007; Blanpain and Fuchs, 2009; McLaren et al., 2009), the roles of their membrane-bound inhibitors is less clear. Based on our observations, we propose that inhibitory receptors sequester ligand on the surface of the cells that produce them to limit the levels of signal available to the stem cell niche. If this model is correct, then the cellular source of secreted stem cell regulators that reside outside of the classical stem cell niche may be identified by the presence of membrane-bound receptors with high levels of surface-localized ligand. Understanding how these cells regulate stem cell function will be critical for treating stem cell–based diseases and for future development of effective stem cell replacement therapies.

Materials and methods

Fly strains

boi
genotype [boi], boi
(genotype [boi]), and ihog
(genotype [ihog]) were generated by Exelixis and maintained by the Harvard stock center. boi and boi are loss-of-function alleles expressing 8% and 0.2% of wild-type, full-length boi transcript, respectively, in the ovary (Fig. S1). ihog has been described previously (Yao et al., 2006; Zheng et al., 2010). In the ovary, 10% of full-length wild-type ihog transcript is expressed in ihog mutants (Fig. S1). smo (Chen and Struhl, 1998) and hsc82 (Lee et al., 1992) are null alleles of smo and hsc82, respectively. RNAi directed against boi (boi), boi, and ihog was generated by Clone Co., Ltd., and cloned into pGEX4T-2. smo (FlyBase accession no. FN2), Ci (FlyBase accession no. FN1), and hh (FlyBase accession no. FN2) were created using the pUASt-boi cloning system (Carnegie Institution of Washington). Smo RNAi directed against boi was expressed in apical cells by generating female flies of the genotype boiRNAi#4, boiRNAi#4, and boiRNAi#4, which was created by site-directed excision of bases corresponding to amino acids 456–598 of Boi. pUASt-boiRNAi was created by site-directed excision of bases corresponding to amino acids 604–701 of Boi. pUASt-boiRNAi, pUASt-boiRNAi, and pUASt-boiRNAi were created using the Gateway Drosophila cloning system (Carnegie Institution of Washington). Transgenic flies were generated by BestGene, Inc. pUASt-boiRNAi, and pUASt-boiRNAi map to the second chromosome.

Generation of anti-boi antibodies

Polyclonal anti-boi antibodies were developed from the injection of a GST fusion protein of amino acids 936–1013 (D isoform) in the cytoplasmic domain of all Boi isoforms into Sprague Dawley rats. Epoine identification was aided by the bioinformatics tools Antigenic (Kalosaka and Tacongo, 1991) and ROBOUS (Kall et al., 2007), Disopred (Ward et al., 2004), and Swiss EMBl (Schwede et al., 2003). The construct was generated by amplifying the boi fragment using genomic PCR (5′-CAGGATCCCCAT- CAGAGGCTCACCACAC-3′ and 5′-GATATGCGAGCAGGAGTT- TACTCTGTCGTC-3′) and cloning it into pGEX4T-2.

Immunofluorescence

Fly ovaries were dissected and fixed as described previously (O’Reilly et al., 2008). Wild-type and mutant ovaries were compared directly by dissecting, fixing, and immunostaining with premixed primary and secondary antibodies at the same time. For anti-boi immunostaining, ovaries were fixed in 2% formaldehyde on ice. For nuclear staining, fixed ovaries were incubated for 15 min with Draq5 (Cell Signaling Technology). After staining, ovaries were mounted in Vectashield medium (Vector Laboratories). Primary antibodies were 1:50 rat anti-Boi, 1:2,000 rabbit anti-Vasa (Hay et al., 1990); 1:100 rabbit anti-Hh (Calvados; provided by P. Therond, Institute of Developmental Biology and Cancer, Université Nice, Sophia Antipolis, Parc Valrose, France; Gallet et al., 2003); 1:100 goat anti-Hh (Santa Cruz Biotechnology, Inc., 1:25 mouse anti-Fas3 (Developmental Studies Hybridoma Bank [DSHB]; Patel et al., 1987); 1:100 rabbit anti-phospho-histone H3 (Millipore); 1:100 mouse anti-Pc (DSHB; Capdevila et al., 1994); and 1:100 mouse anti-Smo (DSHB; Lum et al., 2003b). Secondary antibodies used were FITC, Cy3, and Cy5 conjugated to species-specific secondary antibodies (Jackson Immunoresearch Laboratories, Inc.). Samples were mounted in Vectashield mounting medium. Images were collected at room temperature (−22°C) using 40× (1.25 NA) or 63× (1.4 NA) oil immersion lenses (Leica) on an upright microscope (DM 5000; Leica) coupled to a confocal laser scanner (TCS SP5; leica). LAS AF SP5 software (Leica) was used for data acquisition. Images representing individual channels of single confocal slices from the center of each gerarium were exported as TIFF files, and images were converted to figures using Photoshop software (Adobe). For analysis of Boi expression in wild-type or mutant tissue, ideal settings were determined for immunostaining with wild-type tissue, and the level of signal in boi mutants was compared. To ensure that residual Boi expression was not observed in mutant tissue, the images presented were taken at higher gain than the wild-type tissue, resulting in slightly higher background levels than observed in the wild type.

RNA isolation and quantitative RT-PCR

For RNA isolation, whole ovaries were dissected from female flies. Ovaries were lysed with a dounce homogenizer and RNA isolation was analyzed with a real-time PCR kit (Qiagen). RNA concentrations were determined with a spectrophotometer (NanoDrop, Thermo Fisher Scientific). For each sample, two reverse transcription reactions were performed with 100 and 20 ng of input RNA. 5′ nuclease assays using TaqMan chemistry were run on a sequence detection system (7900 HT; Applied Biosystems). Ct (cycle threshold) values were converted to quantities (in arbitrary units) using standard curve (five points, fivefold dilutions) established with a calibrator sample. Quantitative real-time PCR results were normalized to Rpl13a 40 mRNA levels. For each sample, the two values of relative quantity (from two PCR assays) were averaged, and a representative sample from three independent biological assays is shown. Full-length Boi oligos: forward, 5′-TGGATTGGGATACGAGTGATACGCTG-3′; and reverse, 5′-GGCTTGCTGCTGTCTTTCCA-3′. Full-length ihog oligos: forward, 5′-AAAAACAGCACACAGAGAGG-3′; and reverse, 5′-ACTCATATGACGTCTTGCATGAC-3′. Protein isolation and Western blot

For protein isolation, whole ovaries were dissected from female flies, and ovaries were lysed with a dounce homogenizer and RIPA buffer (50 mM Tris, pH 8.0, 1% SDS, 1% Triton X-100, 150 mM NaCl, 1% deoxycholic acid, 2 mM PMSF, and protease inhibitors [Sigma-Aldrich]). Proteins were run on an 8% SDS-PAGE gel, then transferred to an Immobilon-P (Millipore) membrane. Proteins were probed with anti-Boi antibodies and β-ubulin (EMD).
To measure dividing prefollicle cells, the total number of prefollicle cells was counted and a ratio of PH3+/total was determined. Statistical differences were determined using the Wilcoxon two-sample test, with significance achieved at P ≤ 0.05. To determine the number of dividing follicle cells and FSCs per gerarium, 75–150 geraria were scored for follicle cell number (not touching a germ cell). Follicle cell number (not touching a germ cell) was measured at the border of gerarial regions 2A and 2B, low-level expression of Fas3 (Fas3r), a marker for prefollicle cells, and the presence of a triangular nucleus, a feature that distinguishes FSCs from their daughter cells and neighboring escort cells [Nystul and Spradling, 2007]. The number of PH3+ dividing FSCs was compared with controls (w1118, 109-30/Cyo, or bab-Gal4/+ or boi/+ mutants (boi/boi, boi/+; 109-30/Cyo, or boi/boi; bab-Gal4/+). To measure dividing prefollicle cells, the total number of prefollicle cells that express high levels of Fas3 was determined by counting nuclei stained with Draq5. The number of PH3+ prefollicle cells in the same germlia was counted and a ratio of PH3+/total was determined. Statistical differences were determined using the Student’s t test for two samples, with significance achieved at P ≤ 0.05.

Online supplemental material
Fig. S1 shows that insertion of transposable elements in boi intron 2 significantly reduces expression of boi mRNA. Fig. S2 shows expression of GAL4 transgenes in prefollicle cells or their progeny. Fig. S3 shows normal Hh transcription and increased Ci activity in boi mutants. Online supplemental material is available at http://www.jcb.org/cgi/content/full/jcb.201007142/DC1.

We thank J. Valvardi, J. Hittle, S. Litwin, M. Andrade, and K. Trush for critical comments; P. Therond for the anti-Hh Calvados antibody, A. Tulin for critical comments; P. Therond for the anti-Hh Calvados antibody, and R. Greenberg for fly strains. This study was supported by grants from Fox Chase Cancer Center (to A. O’Reilly), Commonwealth of Pennsylvania Ben Franklin Technology Development Corporation (to A. O’Reilly), and National Institutes of Health (CA06927 [F01/Chase Cancer Center], DK076430-01 to T.R. Hartman, and N5053777 to A. Okada). Submitted: 26 June 2010
Accepted: 26 October 2010
