ABSTRACT

Using the high resolution cosmological \textit{N}-body simulation MareNostrum Universe we study the orientation of shape and angular momentum of galaxy-size dark matter haloes around large voids. We find that haloes located on the shells of the largest cosmic voids have angular momenta that tend to be preferentially perpendicular to the direction that joins the centre of the halo and the centre of the void. This alignment has been found in spiral galaxies around voids using galaxy redshift surveys. We measure for the first time the strength of this alignment, showing how it falls off with increasing distance to the centre of the void. We also confirm the correlation between the intensity of this alignment and the halo mass. The analysis of the orientation of the halo main axes confirms the results of previous works. Moreover, we find a similar alignment for the baryonic matter inside dark matter haloes, which is much stronger in their inner parts.

Key words: dark matter – galaxies: haloes – large-scale structure of Universe – cosmology: theory – methods: \textit{N}-body simulations – methods: statistical

1 INTRODUCTION

Understanding how the angular momentum is distributed over the collapsed structures in the Universe and its connection with the large-scale structure distribution of galaxies at present is a key issue to determine its origin (see Primack 2003, for a review). Furthermore, angular momentum is fundamental in order to explain the structure and dynamics of galaxy discs and hence it is a basic ingredient to determine their evolution and morphology. The currently accepted paradigm for explaining the origin of the angular momentum is the Tidal Torque Theory (Peebles 1969; Doroshkevich 1970; White 1984), hereafter TTT. In this framework, the angular momentum is transferred to the protohalo by the coupling of the quadrupolar inertia tensor and the tidal tensor during the linear regime of growth of density fluctuations. According to TTT, the epoch of turnaround marks a major change in the amount of angular momentum transferred, as this tidal torquing becomes inefficient due to the small size of the halo after it collapses. However the theory breaks at this epoch as non-linear effects are expected to turn up together with merger and accretion processes. In particular, this causes the dilution of the TTT prediction regarding the spin direction (Porciani et al. 2002; Peirani et al. 2004).

None the less, recent observational studies have found a preferential orientation of galaxy discs with respect to their surrounding large-scale structures (Navarro et al. 2004; Trujillo et al. 2006). Such an alignment is thus expected to be a relic of the alignment already present before the epoch of the turnaround. These works differ both in the methodology and the sample used. For instance, Navarro et al. (2004) used catalogues of nearby galaxies and found an excess of edge-on spiral galaxies highly inclined relative to the supergalactic plane. However this result has two major drawbacks: the sample is limited to galaxies in the vicinity of the Milky Way, which is not very representative of the overall large-scale structure; and the orientation of the large-scale sheetlike distributions like the supergalactic plane is blurred due to redshift distortion at high distances (which can only be determined by redshift). On the other hand, Trujillo et al. (2006) used the largest galaxy redshift surveys up to date (2dFGRS and SDSS) to get the sample, and searched for large voids in these surveys to identify...
spatial orientations not relying on the detection of planes. They found that spiral galaxies located on the shells of the largest cosmic voids have rotation axes that lie preferentially on the surface of the void. As this paper has been written, it has also been found a correlation between the orientation of galaxy discs and local tidal shears using the Two Mass Redshift Survey \cite{Lee2007}.

In addition, $N$-body cosmological simulations have nowadays enough resolution to study whether dark matter haloes also show this alignment. This result is expected as it is commonly assumed that both dark and baryonic matter shared a similar evolution during early epochs and gained the same specific angular momentum before the formation of the disc \cite{Fall1980}. However, even in the case of a positive signal, it is expected to be very weak as dark matter haloes are more affected by torques from neighbouring haloes than baryonic matter concentrated in discs. This has recently lead to numerous studies with a variety of methods to select a homogeneous sample of dark matter haloes with the aim of searching a counterpart of the observational results. For example, in \cite{Avila-Reese1999} a multiscale filter is developed in order to distinguish haloes belonging to filaments or walls. This code infers the morphology of the structure surrounding a halo by calculating the relations between the eigenvalues of the hessian of the density field. In a dynamical approach, \cite{Hahn2007} use the number of positive eigenvalues of the hessian of the gravitational potential to classify the environment in which a halo resides. Both papers conclude that haloes in walls have spin vectors that tend to lie in the plane of the host wall, but haloes in filaments show only a weak trend for their angular momenta to be aligned with the filament direction. However, the method proposed by \cite{Trujillo2006} provides a very clean way to characterize the orientation of the large-scale distribution (i.e. the reference direction to measure any kind of alignment) by using the centre of a large void. This method, besides its robustness in observations with respect to redshift distortion, owes its convenience to the well known fact that the direction of maximum compression (that of the smallest eigenvalue of the deformation tensor) turns out to be very well correlated with the direction of the centre of the void.

The study of this type of alignments is specially interesting in the context of gravitational lensing. A key assumption of this method is that the observed galaxy ellipticity correlations come only from the distortion caused by the gravitational shear, with all the intrinsic terms being negligible \cite{Heymans2006b}. Thus, exploring these cosmological alignments may prove to be useful in order to estimate the contamination from this source in the lensing signal. The importance of angular momentum is also remarkable in semi-analytical modelling of galaxy formation \cite{Avila-Reese1999}. The properties of the galactic discs are usually expected to be related to those of the dark matter haloes in which they are embedded \cite{Mo1998}. However, regarding angular momentum this assumption has been recently questioned \cite{D'Onghia2007}.

In this paper, mainly motivated by the observational result found by \cite{Trujillo2006}, we use a high-resolution cosmological simulation to study the alignment of shape and angular momentum of galaxy-size dark matter haloes in the shells of large voids. Our simulation provides enough statistics to assess the results in \cite{Patiri2006} and \cite{Brunino2007} and for the first time to measure the strength of the alignment signal of the angular momentum in these haloes without performing a previous selection of them, as opposed to \cite{Brunino2007}.

This work is organized as follows. In Section 2 we describe the cosmological simulation and the methodology. The results are presented in Section 3. We summarize and discuss our conclusions in Section 4.

2 MARENOSTRUM UNIVERSE SIMULATIONS AND METHODOLOGY

The cosmological simulation we have used for this study is the MareNostrum Universe \cite{Gottloeber2002}. This non-radiative SPH simulation employs $1024^3$ dark matter particles of mass $8.24 \times 10^9 h^{-1} M_{\odot}$ and $1024^3$ gas particles of mass $1.45 \times 10^8 h^{-1} M_{\odot}$ in a box of $500 h^{-1} \text{ Mpc}$ on a side. The cosmological model is $\Lambda\text{CDM}$ with cosmological parameters $\Omega_\Lambda = 0.7$, $\Omega_m = 0.3$, $\Omega_{\text{bar}} = 0.045$, $h = 0.7$, $\sigma_8 = 0.9$ and a slope $n = 1$ for the initial power spectrum. The evolution of the initial conditions was performed by using the TREEPM+SPH code GADGET-2 \cite{Springel2005}. The spatial force resolution was set to an equivalent Plummer gravitational softening of 15 $h^{-1}$ comoving kpc, and the SPH smoothing length was set to the 40$^\text{th}$ neighbour to each particle. The long range gravitational force calculation was done by the Particle-Mesh algorithm using FFT in an homogeneous mesh of $1024^3$ elements.

In this work we use both dark matter and gas particle distributions of this simulation. In order to test the effects of the baryonic component in the results of our analysis, we have also used the results of an N-body, dark matter only version of the MareNostrum Universe. This simulation has exactly the initial conditions and parameters than the SPH simulation but with $1024^3$ dark matter particles only.

Dark matter haloes are found using a parallel hierarchical friends-of-friends algorithm based on the minimum spanning tree for the particle distribution with linking parameter $b = 0.17$, which corresponds to overdensity $\Delta = 330$ with respect to mean matter density. Using equation 2 in \cite{Bailin2005}, and taking into account that the mean axis ratios for galaxy-size haloes are $c/b \simeq 0.79$ and $b/a \simeq 0.75$, we find that about 65 particles are enough to determine main axes orientations to within $15^\circ$. As this is a reasonable resolution, we are restricted to use haloes with $M > 5.4 \times 10^{11} h^{-1} M_{\odot}$, so we will choose our lower mass limit above this value. There are 881,861 haloes in the entire simulation box above this mass at $z = 0$, which provides very good statistics for our purposes.

The detection of voids is made using the HB void finder \cite{Patiri2006}. This code searches for the maximal non-overlapping spheres which are larger than a given radius and empty of objects below a given mass. Those spheres are our voids. We are interested only in large voids, i.e. those with $R_{\text{void}} > 10 h^{-1} \text{ Mpc}$, which characterize the orientation of the large-scale distribution at the position of the halo. We searched for voids defined by haloes with masses larger than $7.95 \times 10^{11} h^{-1} M_{\odot}$, whose axes are resolved to within $15^\circ$. The mass limit has been chosen to get the same number density of haloes as the number density of galax-
ies found in the observed galaxy samples of Trujillo et al. (2006) \(n = 5 \times 10^{-3}\) h\(^{-1}\) Mpc\(^{-3}\), which corresponds to galaxies brighter than \(M_{\text{b}20} \geq -19.4 + 5 \log h\). With this defining mass we found a total of 3047 voids, with a median radius of 11.17 h\(^{-1}\) Mpc. For further comparison with the observational result, we look for Milky Way-sized haloes in a shell of 4h\(^{-1}\) Mpc around the surface of each void. We thus remove all the haloes with mass below the defining mass of the voids 7.95 \times 10^{11} h^{-1} M_{\odot} (which is greater than our resolution limit), and those with mass exceeding 7.95 \times 10^{12} h^{-1} M_{\odot}, so that they are still galaxy-size. Considering all these constraints, we are finally left with 88,426 haloes in the shells of voids and in this range of mass for our analysis.

For every halo we calculate its total angular momentum,

\[
L = \sum_k m_{\text{halo}} \times v_{\text{halo}}^k
\]

where \(v_{\text{halo}}^k\) has its origin in the centre of mass of the halo and the sum is over every dark matter particle identified by the halo finder as belonging to the halo. The orientation of the angular momentum with the centre of the void is given by the angle derived from:

\[
\cos \theta = \frac{R \cdot L}{|R| |L|}
\]

where \(R\) is the vector linking the centre of mass of the halo with the centre of the void, \(R = r_{\text{halo}} - r_{\text{void}}\). In the same way we use an analogous equation to calculate the angle between \(R\) and the major \((a)\), middle \((b)\) and minor \((c)\) halo axis, i.e. the three main axes resulting of the diagonalization of the inertia tensor of haloes in the shells of the voids (the eigenvalues will be referred to as \(a, b \) and \(c\)). This tensor is defined as:

\[
I_{ij} = \sum_k x_{i,k} x_{j,k}
\]

where the coordinates \(x_{i,k}\) represent the \(i\)-th component of the position vector of the \(k\)-th particle, measured with respect to the centre of mass of the halo. This sum is again over halo particles (see Patiri et al. 2006b).

\section*{3 RESULTS}

The main results are summarized in Fig. 1 and Table 1. We show in Fig. 1 the probability density distribution of the orientations of the three main axes and angular momentum of haloes in the shells of voids (using a spherical shell of 4h\(^{-1}\) Mpc around the surface of the void), with respect to the direction to the centre of the void. The angles are calculated using equation 2 and the analogous ones for the main axes correspondingly.

We also plot an analytical fit of the probability density distribution (Betancort-Rijo & Trujillo, in preparation) given by the following equation:

\[
P(\mu) d\mu \propto \frac{p^2 d\mu}{(1 + (p^2 - 1) \mu^2)^{3/2}} ; \quad \mu \equiv \cos \theta
\]

where \(p\) is a free parameter. Although this equation was proposed to describe how the orientation of angular momentum is distributed, it proves to be a very good fit for the distribution of the orientations of the halo main axes.

The distribution of an isotropic distribution is computed and also shown in Fig. 1. If these vectors have no particular orientation (our null hypothesis), then the expected probability distribution is a sine function. We use this fact to represent the deviation of the probability distributions with respect to the isotropic case, so that the null hypothesis corresponds to the zero level in this plot.

In order to quantify the strength of these alignments, we use the parameter \(p\) in Eq. 4 as previously done by Bruno et al. (2007). The null hypothesis corresponds to \(p = 1\), so that \(\mu\) is uniformly distributed. Lower and higher values of \(p\) correspond to a preferential orientation parallel and perpendicular to the centre of the void respectively. A good approximation for this parameter in the case \(p \approx 1\) comes from the relation:

\[
\langle \cos \theta \rangle = \frac{1}{1 + p}
\]

where the average is taken over all the halo sample in the shells of voids.

The results presented in Table 1 are for the three main axes and angular momentum of haloes in the shell of 4h\(^{-1}\) Mpc around the surface of the void. The first column shows the result of averaging the cosine values of the angles considered here for our sample of haloes. The second column shows the result of the statistical test performed here, i.e. the average of the cosine test. In the case of isotropic orientations, the average of the cosine is normally distributed with mean 0.5 and variance \(1/(12N)\), where \(N\) is the number of haloes. Therefore, the bigger is the departure from the mean and the bigger the statistics, the higher the significance of rejecting the null hypothesis, \(N_{\sigma} = \sqrt{12N} (\langle \cos \theta \rangle - 0.5)\). The third column represents the strength of the alignment using the aforementioned parametrization, estimated from a Levenberg-Marquardt fit to our data using Eq. 4. The fourth column also represents the value of \(p\) but this time it is estimated using Eq. 3. The error bars in this parameter correspond to the 68\% confidence level. The last column shows that the value of the reduced \(\chi^2\) is indeed near to unity, which proves the goodness of the fit. It is important to remark that the statistical test only quantifies the probability of isotropy in these orientations; the magnitude of the alignment is indeed measured by the parameter \(p\).

We find for this sample of haloes that the minor axis is preferentially aligned with the direction to the centre of the void, and the major axis is preferentially aligned perpendicular to it. Middle axis also shows an alignment orthogonal to the radial direction, but much weaker than previous one. This confirms the results reported by Patiri et al. (2006b) and Bruno et al. (2007). The same conclusion holds from the analysis of the gas particles embedded in dark matter haloes, although in this case middle axis does not show any significant alignment.

In order to characterize the complete statistical information about the spatial orientation of these haloes, we studied the distribution of the Euler angles. These angles link two orthogonal systems defined at location of each halo in the shell of a void: the one formed by the direction to the centre of the void and any two perpendicular directions that lie in the shell \((\mathbf{X}, \mathbf{Y}, \mathbf{R})\), and the one formed by the three main axes derived from the diagonalization of the inertia tensor of the halo \((\mathbf{a}, \mathbf{b}, \mathbf{c})\). The second coordinate system...
Figure 1. Probability density distribution (measured with respect to the case of isotropic orientations) for the angles between the angular momentum of dark matter haloes in the shells of voids, the three principal axes of these haloes, and the direction to the centre of the void. The error bar on each bin represents the Poissonian error. The dashed line shows a fit of the data using Eq. 4, and the dotted line represents the null hypothesis. Taking haloes in the shells of spheres with randomly distributed centres makes the results agree with isotropy.

Table 1. The strength of the alignment of the three main axes and angular momentum vector of haloes (and baryons embedded therein) in a shell of 4\(h^{-1}\) Mpc around large voids, with respect to the direction to the centre of the void. First column shows the average of the cosine of the angles between these vectors and the radial direction \(R\). Second and third columns show the value of the parameter \(p\) from a fit to Eq. 4 and using Eq. 5 respectively. The fourth column shows the goodness of this fit. The last column represents the result of the statistical test for the rejection of the null hypothesis in terms of \(N_\sigma\) (see text for details).

| Axis       | \(\langle \cos \theta \rangle\) | \(p_{\text{fit}}\) | \(p_{\text{estimated}}\) | \(\frac{\chi^2 - N_\sigma - 1}{2N_\sigma + f}\) | \(N_\sigma\) |

| middle     | 0.5042                          | 0.980 ± 0.010       | 0.983 ± 0.011             | -1.15                            | +1.5        |
| \(L\)      | 0.4922                          | 1.030 ± 0.011       | 1.032 ± 0.011             | +3.20                            | -2.8        |

can be obtained from the first by means of a set of three rotations: a rotation of angle \(\phi\) about \(R\), a rotation of angle \(\omega\) about the rotated \(X\) axis (which places the \(R\) axis in the direction of \(\alpha\)), and finally a rotation of angle \(\psi\) about this \(\alpha\) axis, which places the other two in the direction of \(b\) and \(c\). It is important to remark that \(\omega\) is actually the angle between the major axis and the direction to the centre of the void, so we already know its distribution. Moreover, due to the rotational symmetry about the direction \(R\) (there is no privileged point in the surface of a sphere), we also know...
that $\phi$ is uniformly distributed. Thus, for a complete description of the spatial orientation of our haloes we need to find out the distribution of the $\psi$ angle. Obviously if the shape of the haloes were not aligned with any particular direction, $\psi$ would be uniformly distributed. Nevertheless we find that the distribution of this angle is instead well described by (Betancort-Rijo & Trujillo, in preparation)

$$P(\psi) \, d\psi = \frac{2}{\pi} (1 + \beta \cos(2\psi)) \, d\psi$$

(6)

where $\beta$ is a free parameter. A fit of our data gives $\beta = -0.093 \pm 0.005$. However, if we select a sample of those haloes whose major axis forms an angle with $R$ above a given value $\omega_0$, this parameter seems to rise. This is an indication that in fact, the distribution of $\psi$ is not independent of this angle, and the complete description of the shape alignment will be given by a more general distribution $P(\omega, \psi)$.

But our most remarkable result is that we find a previously undetected alignment of angular momentum, whose orientation is preferentially perpendicular to the direction to the centre of the void (but not necessarily aligned with the major axis). This is confirmed by the average of the cosine and a Kolmogorov–Smirnov test. Although this alignment is small, both statistical tests agree in rejecting the null-hypothesis with a probability corresponding to a significance level of more than 7$\sigma$.

Previous studies have not found such an orientation of the angular momentum in the shells of voids, mainly because of the poor halo statistics due to the small simulation box. For instance, the halo sample in Patiri et al. (2006a) consisted of only 1729 objects with which they managed to find $p = 0.96 \pm 0.04$. Despite this value is compatible with our result, it points that angular momentum tends to be aligned with the direction to the centre of the void, which is the opposite of what we find. Box size may also have been the reason why Heymans et al. (2006) could not reject the null hypothesis (causing the error bars to be about a factor of two larger than those shown in our Fig. 4, although other factors may have had some influence on their conclusions, like the small number of particles in their haloes or their estimation of error bars via bootstrap method. The case of Brunino et al. (2007) is specially surprising, since having the same box size, the resolution of Millennium simulation largely exceeds that of this paper. Yet, they still find that the distribution of the angular momentum is compatible with a random orientation. Taking a convenient subsample of haloes they found a significant alignment, but only in one out of the seven radial bins considered. This subsample is obtained selecting haloes with a disc-dominated galaxy at their centre, using semianalytic galaxy catalogue of Croton et al. (2006). The galaxy must be brighter than $M_K < -23$ and have a bulge to total ratio $0 < B/T < 0.4$. On the contrary, it is noteworthy that no preselection was performed for the results presented here.

The likely explanation for this disagreement is that their haloes were identified with the same halo finder but with a linking length which corresponds to an overdensity 900 times the mean matter density, to focus on the core properties of the haloes. Here, we compute main axes and angular momentum of haloes detected with a linking length corresponding to 330 times the mean matter density (see Section 2). For comparison, we show in Table 2 the results of the same analysis as in Table 1 but using a catalogue of haloes in our simulation box defined by an overdensity eight times higher. Although the main axes show a stronger alignment in the inner parts of the halo, it is clear that the alignment of the angular momentum with the direction to the centre of the void is lost when we focus in the inner parts. The contribution to the angular momentum from the particles in the outer shells of a halo is then fundamental for this conclusion. It is quite remarkable that the gas in the inner part does not show this alignment either, despite the fact that both major and minor axes show an enhanced alignment compared to dark matter haloes.

As a further test of our results we repeated the analysis to obtain the strength of the alignments, by taking haloes in the shells of fake voids (i.e. spheres with randomly distributed centres throughout the simulation box). The results for both shape and angular momentum alignment are then compatible with the null hypothesis. To test the effect of baryons in the alignments of dark matter haloes we have analysed the dark matter only version of the MareNostrum Universe. The results we obtain for the strength of these alignments are compatible to those listed in the upper (dark matter) part of Table 1 and Table 2.

We also studied the dependence of the strength of these alignments when moving outside the surface of the void. The results are shown in Table 3. In this table we show the value of the parameter $p$ estimated using Eq. (3) along with their error bars, in several different shells surrounding the void. The shells are selected for direct comparison with Brunino et al. (2007). It is clear from the table that the strength of the alignments dilutes as we move outside the surface of the void. The inner shell show a weaker alignment of the angular momentum compared to that work. Instead, this strength declines slower here as we advance to the outer shells. This is in contradiction with the statement in Brunino et al. (2007) suggesting that taking a wide shell can mask this alignment. Interestingly, we find that the alignment of the angular momentum is still significant even at few times $R_{\text{void}}$.

Some studies have suggested that voids are not generally spherical, so that alignment detections assuming spherical voids should therefore be seen as residual of genuine physical alignments (e.g. Aragón-Calvo et al., 2007). However, using an ellipsoidal void catalogue for the MareNostrum Universe we find similar results for the orientation of angular momentum and main axes for the haloes in the shells of those non-spherical voids (see Table 3). Moreover, we find no significant difference between the direction to the centre of the void and the direction perpendicular to the ellipsoid, taking $n \equiv (R \cdot a/a^2, R \cdot b/b^2, R \cdot c/c^2)$ as the reference direction for angle measurements. Dark matter haloes selected here are located in a shell of $4h^{-1}$ Mpc thick around the maximal sphere enclosed into the ellipsoid. In order to study more in depth the relevance of void shape, we studied the probability distribution function of the Euler angle $\phi$. In the case of spherical voids, this angle is uniformly distributed due to the rotational symmetry in the plane tangential to the sphere at the position of the halo. On the other hand, this symmetry is broken in the case of ellipsoidal voids, so the distribution of the $\phi$ angle might be different. However, taking into account that
In agreement with the alignment of the angular momentum with the mass of uniform distribution. We find
\[ \langle \cos \theta \rangle \]
using two different void catalogues in the same simulation. For the normal direction to the centre of the void for haloes in a shell of 4\,h^{-1}\,Mpc.

The strength of dark matter halo alignments measured from parameter \( p \) at 1\,\sigma confidence level using different shells around the surface of the void. Recall that the null hypothesis (isotropic orientations) corresponds to \( p = 1 \). Lower and higher values of \( p \) correspond to a preferential orientation parallel and perpendicular to the centre of the void respectively.

### Table 2

### Table 4

| Axis         | Spherical Void Catalogue | Ellipsoidal Void Catalogue |
|--------------|-------------------------|-----------------------------|
| Major        | 1.110 ± 0.004           | 1.112 ± 0.004               |
| Minor        | 0.884 ± 0.003           | 0.886 ± 0.004               |
| Middle       | 1.023 ± 0.004           | 1.021 ± 0.004               |
| \( L \)      | 1.029 ± 0.004           | 1.028 ± 0.004               |

\[
\sin \phi = \frac{v \cdot \hat{i} - (v \cdot R)(\hat{i} \cdot R)}{\sqrt{1 - (v \cdot R)^2} \sqrt{1 - (\hat{i} \cdot R)^2}}
\]

where \( \hat{i} \) is defined in the direction of the major axis of the void and \( v \) in the direction of the major axis of the halo, we find \( \langle \phi \rangle / (\pi/2) = 0.5001 ± 0.0009 \) in agreement with a uniform distribution.

There also have been recent claims of dependence on the alignment of the angular momentum with the mass of the halo in filaments and walls of the large-scale structure (Aragón-Calvo et al. 2007; Hahn et al. 2007a). In agreement with these works we find a slight trend of increasing alignment strength with halo mass for our sample. Using a shell of 4\,h^{-1}\,Mpc the haloes near the resolution limit imposed, with \( M = 5 \times 10^{11} - 8 \times 10^{11} h^{-1} M_\odot \), have a strength value of \( p \approx 1.015 \). On the other hand, haloes with masses in the upper limit of the sample \( M = 8 \times 10^{12} - 2 \times 10^{13} h^{-1} M_\odot \) show evidence of a stronger alignment with \( p \approx 1.060 \).

### 4 Discussion and Conclusion

In this paper we have analysed the orientation of main axes and angular momentum of dark matter haloes in the shells of large voids using the MareNostrum Universe simulation. The spins of these haloes are preferentially perpendicular to the direction to the centre of the void. The possibility of isotropic orientations has been rejected at 7\,\sigma confidence level. This result is in qualitative agreement with and is likely to be related to the observational result of Trujillo et al. (2006) for spiral galaxies using large galaxy surveys. The alignment of dark matter collapsed structures with the large-scale structure might be a relic of the angular momentum acquired by dark and baryonic matter during growth of density fluctuations in the early Universe, and hence have a cosmological origin. However, this alignment may also be related with the fact that the surrounding filaments represent a preferential direction of infall (e.g. Colberg et al. 2003), which could be a feasible explanation for this signal (Vivitskia et al. 2002). Note that also the tidal field may pull these haloes toward a realignment of their shape and their spin (Altay et al. 2006; Aragón-Calvo et al. 2007).

This is the first time that this alignment has been found in cosmological simulations using haloes in the shells of voids, in contrast to previous results. The poor halo...
statistics in the simulation box, the small number of particles in haloes, and even an overestimation of the error bars are likely to be the causes of the non-detection of this effect in [Patiri et al. (2006)] and [Heymans et al. (2006)]. [Brunino et al. (2007)] did not succeed in finding this alignment either, and concluded that the distribution of angular momentum vectors is compatible with isotropy for their total dark matter halo sample. This is somewhat surprising since they used the Millennium simulation which exceeds the resolution of the MareNostrum Universe simulation used here, having both the same box size. However, we have checked that the uncertainties in the orientation of the vectors used here are small enough to ensure the accuracy of these results. We recall that the haloes used here are chosen to be well resolved and their directions are determined to within an angle of 13°. Indeed, it can be proven that this small indetermination in the angle measurement makes the uncertainty in the parameter p be negligible. It is very likely that the linking length (and hence the overdensity) used to identify the haloes in the simulation box makes the results to differ as we have shown in Section 3. The choice of an overdensity 900 times the mean matter density (as opposed to our selection of overdensity 330) allowed them to focus only in the inner parts of the halo, but this may have prevented them from the detection of the alignment of the angular momentum we found. This suggests that the particles in the outer shells of the halo are determining in the measurement of the strength of this alignment.

None the less, the claim of [Brunino et al. (2007)] that they found a significant alignment at the surface of the void, is based only in the choice of a subsample based on a semianalytic galaxy catalogue. As we have mentioned above, they do not find any preferential orientation in their total sample. Moreover, we find that this alignment is significant even at few times R_{void}.

Our main result that galaxy-size dark matter haloes around voids have spins that lie in the shells of voids, is in agreement with that of [Aragón-Calvo et al. (2007)], if haloes in the shells of void which form large-scale sheets are mainly responsible for this effect. However, [Hahn et al. (2007)] found a stronger alignment of haloes in sheets than largely exceed the one presented here. Nevertheless, haloes around voids are located in a less dense environment than actual sheet haloes, which may have influence on their orientation.

Shape alignment of haloes in the surface of large voids is further confirmed, as shown previously by [Patiri et al. (2006)]. Minor axis is found to be preferentially aligned with the direction to the centre of the void and major axis tends to be aligned with the orthogonal direction. These results are also robust with respect to the shape of the void. Using an ellipsoidal void catalogue and measuring angles with respect to the radial and the normal direction we do not find any difference compared to the results obtained using spherical voids for the orientation of the main axes and angular momentum. Hence, we do not find that the shape of the void is meaningful for this purpose. We also analysed the strength of these alignments in several shells around the surface of the void. Comparing our results with those in [Brunino et al. (2007)], we find a systematically weaker alignment in the shape orientation of dark matter haloes.

Regarding gas particles, we find that the angular momentum of baryons is oriented with respect to the radial direction with a strength similar to dark matter, even considering the inner parts of the halo. However, in the core of the halo shape alignment for gas particles is enhanced with respect to dark matter. Although this is a remarkable result for its observational implications, the effect of cooling and full scale star formation in these orientations remains to be investigated.

In addition, we found a slight trend of the alignment of angular momentum with the halo mass, as in [Aragón-Calvo et al. (2007)]. More massive haloes happen to be more aligned with the orthogonal direction. A possible explanation to this fact could be their recent formation, as pointed out by [Aragón-Calvo et al. (2007)], which makes less massive haloes be more affected by non-linear interactions. It has also been suggested that an alternative explanation is that this effect might be due to the preferred accretion along the filaments [Shaw et al. (2006)].

Evolution of this alignment in cosmological simulations have been studied by [Hahn et al. (2007)]. Unfortunately, it is very difficult to draw a conclusion about the evolution of the alignments from the present data. A deeper analysis of the redshift evolution of the strength of this signal is mandatory to elucidate its origin.

We thank Barcelona Supercomputer Center - Centro Nacional de Supercomputación for the computer time awarded to run the MareNostrum Universe simulations. The analysis of this simulation has been performed in NIC Jülich. A.J.C. enjoyed the hospitality of the Astrophysical Institute Potsdam where part of this work was carried out. A.J.C., J.B.-R., S.G.P. and F.P. thank the Spanish MEC under grant PNAYA 2005-07789 for their support. G.Y. acknowledges financial support to the Spanish PNFP2006-01105 and PNAYA2006-15492-C03. A.J.C. appreciates the financial support of the MEC through Spanish grant FPU AP2005-1826. This work was also partially supported by the Acciones Integradas Hispano-Alemanas.
