Abstract

Background: Both physical activity and sedentary behaviour have been individually associated with health, however, the extent to which the combination of these behaviours influence health is less well-known. The aim of this study was to examine the associations of four mutually exclusive categories of objectively measured physical activity and sedentary time on markers of cardiometabolic health in a nationally representative sample of English adults.

Methods: Using the 2008 Health Survey for England dataset, 2131 participants aged ≥18 years, who provided valid accelerometry data, were included for analysis and grouped into one of four behavioural categories: (1) ‘Busy Bees’: physically active & low sedentary, (2) ‘Sedentary Exercisers’: physically active & high sedentary, (3) ‘Light Movers’: physically inactive & low sedentary, and (4) ‘Couch Potatoes’: physically inactive & high sedentary. ‘Physically active’ was defined as accumulating at least 150 min of moderate-to-vigorous physical activity (MVPA) per week. ‘Low sedentary’ was defined as residing in the lowest quartile of the ratio between the average sedentary time and the average light-intensity physical activity time. Weighted multiple linear regression models, adjusting for measured confounders, investigated the differences in markers of health across the derived behavioural categories. The associations between continuous measures of physical activity and sedentary levels with markers of health were also explored, as well as a number of sensitivity analyses.

(Continued on next page)
In this national sample of English adults, being physically active was associated with a better health profile, even in those with concomitant high sedentary time. Low sedentary time independent of physical activity had a positive association with HDL-cholesterol.

Keywords: Accelerometry, Objective, Physical activity, Sedentary, Cardiometabolic health
V3.3.76 (KineSoft, Loughborough, UK). Accelerometer counts were used to calculate the time spent in each intensity band: sedentary behaviour (<100 counts per min (cpm)), light-intensity physical activity (100–1951 cpm) and MVPA (≥1952 cpm) [38]. In addition, MVPA time accumulated in bouts of ≥10 min, allowing for a two minute exception in the intensity threshold, was also derived. Non-wear time was defined as any periods of continuous zero counts for ≥60 consecutive min [39]. A valid day was defined as ≥10 hours (i.e. ≥600 min) of wear-time. Adults who provided ≥4 days of valid accelerometer data were included.

**Derivation of the behavioural categories**

For each individual, the average number of minutes per valid day spent in MVPA, light-intensity physical activity and sedentary behaviour were calculated. Based upon other studies [36, 40], the sedentary behaviour-to-light-intensity physical activity ratio (average sedentary time ÷ average light-intensity physical activity time) was used for the classification of sedentary status. Participants were then split into quartiles based on this ratio. Given that the levels of sedentary behaviour in the general population are predominantly high [9–12], a conservative, data-driven approach was undertaken and individuals were classified as ‘low sedentary’ if they resided in quartile 1 and ‘high sedentary’ if they resided in quartiles 2, 3 or 4. MVPA status was classified as ‘physically active’ or ‘physically inactive’ on the basis of whether or not participants accumulated at least 150 min of MVPA per week. This allowed the formation of four mutually exclusive behavioural categories (Fig. 1), which are provided with communicative names to aid interpretability: (1) ‘Busy Bees’: physically active & low sedentary, (2) ‘Sedentary Exercisers’: physically active & high sedentary, (3) ‘Light Movers’: physically inactive & low sedentary, and (4) ‘Couch Potatoes’: physically inactive & high sedentary.

**Markers of cardiometabolic health**

A trained interviewer recorded height (measured to the nearest 0.1 cm using a portable stadiometer) and weight (measured to the nearest 0.1 kg using an electronic scale) readings [37]. Body Mass Index (BMI) was calculated as the weight (in kilograms) divided by the square of the height (in metres). Waist circumference was defined as the midpoint between the lower rib and the upper boundary of the iliac crest. A nurse measured this twice to the nearest 0.1 cm using a tape and the mean of the two readings was used [37]. Non-fasting blood samples were collected by the nurse for the analysis of high-
density lipoprotein (HDL) cholesterol, total cholesterol and glycated haemoglobin (HbA1c). Blood analytes were assayed at the Royal Victoria Infirmary laboratory in Newcastle upon Tyne, England. Further details regarding these variables can be found elsewhere [37].

**Contextual variables**

The following factors, collected by a trained interviewer [37], were also utilised: age (in years); cardiovascular disease index (no cardiovascular diseases, one or more cardiovascular diseases); fruit and vegetable consumption (0, 1–3, 4–6, 7+ portions per day); ethnicity (white, non-white); sex (male, female); smoking status (never smoked, ex-smoker, current smoker); socioeconomic status (national statistics socioeconomic classification: low, high-intermediate, intermediate, low-intermediate, low); blood pressure medication (no, yes); cholesterol medication (no, yes); and any other prescribed medication (no, yes). The 'cardiovascular disease index' variable was based on the following physician diagnosed cardiovascular conditions/events: abnormal heart rhythm; angina; atrial fibrillation; congenital heart disease; heart attack; heart transplant; heart valve disease; intermittent claudication; stroke; and transient ischaemic attack.

**Statistical analysis**

All statistical analyses were conducted using Stata/IC V13.1 (Stata Corporation, College Station, Texas, USA) and controlled for the complex survey strategy employed in the 2008 HSE (primary sampling units, clustering and survey weights) [11, 37]. Interview weights, which adjusted for: household selection; non-response bias; age; sex; and regional profiles, were applied in order to produce estimates representing the national population. Nurse weights (generated from interview weights) were utilised to further reduce non-response bias arising from individuals who were interviewed but did not have a nurse visit. Blood weights (generated from nurse weights) were utilised to analyse the blood related variables.

**Categorical associations**

Pairwise deletion was used throughout the study for handling any missing data. The weighted prevalence [n; %] of the English adults in each mutually exclusive behavioural category were computed. Participant characteristics of the full sample, stratified by each category, were tabulated. Categorical variables were presented as proportions [n; %], whereas the continuous variables were summarised via their means and standard errors. Univariate linear regression models, with ‘behavioural category’ as the independent variable, were fitted for the following assessed health markers: BMI; waist circumference; HDL-cholesterol; total cholesterol; and HbA1c. The ‘Couch Potatoes’ category, representing physically inactive adults with high sedentary time (i.e. the least desirable group), was selected as the reference category. Subsequently, multiple linear regression models were also fitted for each dependent variable with the following covariates: age; BMI (except in the model with BMI as the dependent variable); cardiovascular disease index; ethnicity; fruit and vegetable consumption; sex; smoking status; socioeconomic status; and accelerometer wear-time. Models with HDL-cholesterol and total cholesterol as the dependent variable were also controlled for both blood pressure medication and cholesterol medication. Similarly, the model with HbA1c as the dependent variable was controlled for any prescribed medication. All regression analyses were two-sided where \( p < 0.01 \) was considered to be statistically significant to account for multiple comparisons.

The following sensitivity analyses, examining the robustness of the main effects, were also investigated: (1) missing data in the covariates were imputed using the behavioural category means (continuous variables: BMI) and modes (categorical variables: smoking status and socioeconomic status), (2) participants with a cardiovascular disease index of ‘one or more cardiovascular diseases’ were excluded, (3) ‘Low Sedentary’ was defined as residing in the lowest tertile of the ratio between the average sedentary time and the average light-intensity physical activity time, and (4) participants were only classified into the ‘physically active’ categories if they accumulated \( \geq 150 \) min of MVPA per week in bouts of \( \geq 10 \) min. For each sensitivity analysis, the weighted behavioural category prevalence and health associations were reported.

**Continuous associations**

The associations between continuous measures of physical activity and sedentary levels with markers of health were also investigated. Multiple linear regression models were fitted for each health marker whilst controlling for the appropriate corresponding confounders as well as both continuous MVPA time and sedentary status (sedentary-behaviour-to-light-intensity physical activity ratio). Analogous to the categorical analyses, these regression analyses were also two-sided with \( p < 0.01 \) considered to be statistically significant.

**Results**

A total of 2131 adults were available for analysis after retaining only those individuals who provided \( \geq 4 \) valid days of accelerometer data. The four groups were comprised as follows: (1) ‘Busy Bees’: \( n = 385; 18.6 \% \), (2) ‘Sedentary Exercisers’: \( n = 743; 36.7 \% \), (3) ‘Light Movers’: \( n = 147; 6.8 \% \), and (4) ‘Couch Potatoes’: \( n = 856; 37.9 \% \). Table 1 presents the characteristics of the participants.
### Table 1 Participant characteristics

| Characteristic                                      | Sample N = 2131 | 'Busy Bees' n = 385; 18.6 % | 'Sedentary Exercisers' n = 743; 36.7 % | 'Light Movers' n = 147; 68 % | 'Couch Potatoes' n = 856; 37.9 % |
|-----------------------------------------------------|-----------------|-----------------------------|----------------------------------------|-------------------------------|----------------------------------|
| Age (in years)
|                                                     | 50.8 (0.47)     | 44.8 (0.72)                 | 45.6 (0.72)                  | 49.8 (1.27)                  | 58.9 (0.74)                      |
| Cardiovascular Disease Index
| No Cardiovascular Diseases                          | 2030 (95.6)     | 374 (97.4)                  | 707 (95.7)                   | 141 (96.2)                   | 808 (94.6)                       |
| One or More Cardiovascular Diseases                 | 101 (4.4)       | 11 (2.6)                    | 36 (4.3)                     | 6 (3.8)                      | 48 (5.4)                         |
| Ethnicity
| White                                              | 2008 (93.2)     | 364 (93.6)                  | 691 (92.1)                   | 141 (95.1)                   | 812 (93.8)                       |
| Non-White                                          | 123 (6.8)       | 21 (6.4)                    | 52 (7.9)                     | 6 (4.9)                      | 44 (6.2)                         |
| Fruit & Vegetable Consumption (portions per day)
| 0                                                  | 95 (4.5)        | 25 (6.1)                    | 29 (3.9)                     | 8 (5.5)                      | 33 (4.0)                         |

Categorical associations
The unadjusted and adjusted categorical analyses are displayed in Table 2 and Additional file 1: Figure S1. The adjusted analyses showed that in comparison to ‘Couch Potatoes’, ‘Busy Bees’ had significantly lower BMI (p < 0.001), waist circumference (p = 0.007) and HbA1c (p = 0.003) levels, and higher HDL-cholesterol (p = 0.001) levels. Similarly, ‘Sedentary Exercisers’ had significantly lower BMI (p < 0.001) and HbA1c (p = 0.009) levels, and higher HDL-cholesterol (p < 0.001) levels. ‘Light Movers’ had significantly higher HDL-cholesterol (p = 0.004) levels.

The sensitivity analyses, including an alternative less conservative method for classifying sedentary status, indicated robustness and stability. Although the prevalence in each category varied across the different methods

used (Additional file 1: Table S1), the main results from the primary multiple linear regression models were largely unaffected (Additional file 1: Table S2).

Continuous associations

The adjusted continuous analyses are displayed in Table 3 and showed consistency with the categorical analyses. These models, which controlled for relevant confounders as well as both MVPA time and sedentary status, revealed that MVPA time was significantly associated with lower BMI (\(p < 0.001\)), waist circumference (\(p < 0.001\)) and HbA1c (\(p = 0.002\)) levels, and higher HDL-cholesterol (\(p < 0.001\)) levels. In contrast, sedentary status was significantly associated with lower HDL-cholesterol (\(p = 0.004\)) levels.

Discussion

This is the first study to quantify associations of mutually exclusive categories of objectively measured physical activity and sedentary time with markers of cardiometabolic health in a nationally representative sample of English adults. Overall, adults who engaged in at least 150 min of MVPA per week, including those with concomitant high sedentary time (‘Sedentary Exercisers’), had more favourable health profiles compared to physically inactive individuals with high sedentary time (‘Couch Potatoes’). Low sedentary time independent of physical activity (‘Light Movers’) had positive associations with HDL-cholesterol. These findings were consistent with the sensitivity and continuous analyses.

The approach to categorising the population into one of four mutually exclusive categories extends previous research using HSE. For example, previous analysis of HSE has reported associations between both self-reported and objectively assessed sedentary time with markers of health in working age and older adults and between MVPA and markers of health [25–27]. The wider evidence has increasingly demonstrated that objectively measured sedentary time is independently associated with markers of cardiometabolic health [16–20, 41, 42], although not all studies have demonstrated this link [43]. Whilst these previous analyses have adjusted for MVPA, the associations of sedentary time with health across physical activity levels are less well understood. Therefore, this study adds to the evidence by investigating associations of sedentary status with health across categories of physical activity.

Our findings are in broad agreement with the only other study to have used a similar methodology [36]. Using national survey data from the USA, Loprinzi and colleagues found that in comparison to individuals (aged ≥20 years) who engaged in <150 min/week of MVPA with high sedentary time (sedentary time > light-intensity physical activity time), individuals engaging in ≥150 min/week of MVPA had a more favourable cardiometabolic profile (BMI, waist circumference, C-reactive protein, white blood cells and neutrophils) regardless of their sedentary status. [36] Participants in the most desirable group (≥150 min/week of MVPA with low sedentary time) also had better HDL-cholesterol, triglyceride and insulin levels. Similar to our study, participants in the physically inactive group with low sedentary time had fewer beneficial associations, although more favourable profiles for triglycerides and insulin levels were still observed.

Our findings, alongside those of Loprinzi and colleagues [36], are also consistent with the emerging evidence that levels of fitness or physical activity may modify the associations between sedentary time and markers of health in adults [35, 41, 44, 45], with sedentary behaviour only emerging as a determinant of health in those who are inactive or unfit. Together, these studies suggest that being physically active may confer some protection from the potentially deleterious impact of high sedentary behaviour.

In our study, low sedentary time in the absence of being physically active (‘Light Movers’) was associated with

| Health marker                  | Moderate-to-vigorous physical activity time (Beta (99% CI)) | p-value | Sedentary behaviour-to-light-intensity physical activity ratio (Beta (99% CI)) | p-value |
|--------------------------------|------------------------------------------------------------|---------|------------------------------------------------------------------------------|---------|
| Body Mass Index (kg/m²)        | -0.0393 (-0.0505, -0.0282)                                  | <0.001  | -0.1109 (-0.3918, 0.1700)                                                   | 0.305   |
| Waist Circumference (cm)       | -0.0315 (-0.0442, -0.0188)                                  | <0.001  | 0.1380 (-0.2502, 0.5261)                                                    | 0.355   |
| HDL-Cholesterol (mmol/L)       | 0.0019 (0.0009, 0.0029)                                     | <0.001  | -0.0253 (-0.0476, -0.0030)                                                  | 0.004   |
| Total Cholesterol (mmol/L)     | 0.0006 (-0.0024, 0.0036)                                    | 0.606   | -0.0480 (-0.1335, 0.0376)                                                   | 0.146   |
| Glycated Haemoglobin (%)       | -0.0021 (-0.0037, -0.0004)                                 | 0.002   | -0.0079 (-0.0056, 0.0407)                                                   | 0.673   |

All analyses accounted for primary sampling units, clustering and survey weights. Adjusted linear regression models were fitted for each cardiometabolic health marker. The models controlled for: age; body mass index (except in the model with body mass index as the dependent variable); cardiovascular disease index; ethnicity; fruit and vegetable consumption; sex; smoking status; socioeconomic status; moderate-to-vigorous physical activity time; sedentary behaviour-to-light-intensity physical activity ratio; and accelerometer wear-time. Models with HDL-cholesterol and total cholesterol as the dependent variable were also controlled for both blood pressure medication and cholesterol medication. Similarly, the model with glycated haemoglobin as the dependent variable was controlled for any prescribed medication. **Bold** indicates statistical significance at \(\alpha = 0.01\)

\*Beta coefficients represent a one minute increase in moderate-to-vigorous physical activity time per day

\*Beta coefficients represent a one unit increase in the sedentary behaviour-to-light-intensity physical activity ratio
higher levels of HDL-cholesterol (+0.11 mmol/L), suggesting that physical inactivity in a combination with low sedentary time may have some positive relationships with health. However, the potential benefits appeared to be less numerous and consistent than those observed for physically active categories (‘Busy Bees’ and ‘Sedentary Exercisers’). One reason for this could be in the assessed markers of cardiometabolic health. Although our study included a measure of glycaemia (HbA1c), more sensitive measures of insulin resistance, which have shown stronger associations with sedentary time [6, 19, 20, 46], were not available.

Although sedentary behaviour and MVPA have been hypothesised to be distinctive health behaviours, it is unclear to what extent the underlying mechanisms act through the same or independent pathways. This reflects a limitation in the evidence more generally where mechanisms underpinning the benefits of sedentary behaviour have not been adequately elucidated. To date, the only evidence-based independent mechanism for sedentary behaviour has been through the activation of lipoprotein lipase which has been shown to change by a factor of 10 in animal models following hind limb suspension [47]. This supports the observation in our study where low sedentary time was associated with higher HDL-cholesterol levels, even in those who were physically inactive (‘Light Movers’). In contrast to sedentary behaviour, acute and chronic physiological adaptations have been well established linking higher levels of physical activity to cardiometabolic health [48–50].

Strengths and limitations
Our study has several strengths and some limitations. Strengths include; exploitation of a well-characterised national survey which employs a multifaceted stratified random sampling procedure; utilising objectively measured physical activity and sedentary behaviour data; and a wide range of sensitivity analyses to test the robustness of our findings. The method used for deriving sedentary status has both strengths and limitations in itself. In contrast to Loprinzi and colleagues [36], who used a pre-defined method for classifying high/low sedentary time, we took a conservative, data-driven approach. Differences between accelerometer characteristics, such as wear-time, across populations can have a significant effect on the average sedentary time, artificially inflating or deflating the number of participants falling within a fixed threshold. For example, based on the method used by Loprinzi and colleagues [36], less than 8% of the participants in our sample would be classified as ‘Low Sedentary’, and only 1.6% of the population would be categorised as physically inactive with low sedentary time i.e. ‘Light Movers’ (data not shown). Therefore, the approach used in our study ensures that the categories are determined in relation to the population characteristics and not influenced by measurement artefact. However, the corresponding limitation is that specific targets for intervention are difficult to define. Additional pertinent limitations that are applicable to our study include the cross-sectional design which prohibits the possibility of establishing causality (reverse-causality remains open) or that unmeasured variables were confounding observed associations. Other factors which may limit the generalizability of the findings include: the relatively small sample size for a national survey; the ethnically heterogeneous white population; non-fasting measures of HDL-cholesterol and total cholesterol; and moderately high proportions of missing data in the blood analytes, particularly for HbA1c. Furthermore, a larger sample would have allowed for more dose–response categories. Lastly, our accelerometer data are based on classifying horizontal movement intensity and cannot distinguish between different postures (i.e. sitting and standing).

Conclusions
In conclusion, we demonstrate that in comparison to adults who are physically inactive with high sedentary time, those who are physically active have a more desirable health profile across multiple cardiometabolic markers even when combined with high sedentary time. In contrast, low sedentary time in the absence of physical activity is associated with higher HDL-cholesterol levels. By suggesting that being physically active may offset some of the deleterious consequences of a routinely sedentary lifestyle, this study further emphasises the importance of physical activity in the promotion and maintenance of health. However, given the observational design, the interaction and relative magnitude of effect of physical activity and sedentary behaviour on health needs further elucidation through experimental research in order to better inform public health policy and guidance.

Availability of data and materials
Permission to use the 2008 Health Survey for England accelerometer data files can be obtained from the National Centre for Social Research (Natcen) (http://www.natcen.ac.uk/).
