ABSTRACT

We present far-ultraviolet spectra of the Seyfert 2 galaxy Mrk 533 obtained with FUSE. These spectra show narrow asymmetrical O VI λλ1032,1038 emission lines with stronger wings shortward of the peak wavelength, but the degree of asymmetry of these wings in velocity is much lower than that of the wings of the lines of lower ionization. In the combined O VI profile there are marginal indications of local absorptions in the outflow. The C IIIλ977 line is seen weakly with a similar profile, but with very low signal to noise. These FUV spectra are among the first for a Seyfert of type 2, i.e., a purportedly obscured Seyfert. The HST STIS spectral image of Mrk 533 allows delineation of the various components of the outflow, and we infer that the outflow is accelerated. We discuss the results in terms of nuclear geometry and kinematics.

Subject headings: active galaxies: general — active galaxies: individual (NGC 7674; Mrk 533)
1. INTRODUCTION

Seyfert (Sy) galaxies have been long-recognised as a class of active galactic nuclei (AGN) that occupy the low end of the AGN luminosity range. They are primarily characterized by strong optical emission lines with implied Doppler broadening $\gtrsim 300 \text{ km s}^{-1}$, and a wide range of ionization (e.g., Osterbrock 1989). They are also characterized by strong X-ray emission (e.g., Elvis et al. 1978). In addition, Seyferts are usually radio-quiet, are in spiral host galaxies, and have central luminosities below the commonly adopted limit for quasars of $M_B^\text{total} = -23$ (e.g., Schmidt & Green 1983).

Seyferts have traditionally been classified into types 1 and 2, distinguished primarily by the clear presence or absence of a component to the permitted lines in their spectra that is significantly broader than their forbidden lines. The Unified Scheme (e.g., Antonucci, 1993) attempts to unify the two Seyfert types by hypothesizing a ubiquitous obscuring torus around their nuclei; the central emission (including the broad permitted line component) is then obscured when the Seyfert is oriented with its torus edge-on, and it appears to us as a Sy 2. When the torus is pole-on, the broad emission lines from the central clouds are directly visible, and the Seyfert is classified as of type 1. The Unification Scheme found particularly strong support in the discovery of weak polarized broad lines from Sy 2s (Antonucci & Miller 1985; Moran et al. 2000), which are interpreted as originating from the hidden clouds but scattered periscopically into our line of sight.

The Unification Scheme is conceptually appealing and many observational results are consistent with its predictions, including, (i) the detection in Sy 2s of broad lines of $\text{Pa}_\beta$, to which the torus is expected to be transparent (Veilleux et al. 1997), (ii) the paucity of measured ionizing photons in Sy 2s, consistent with the torus attenuating the ionizing continuum emitted along our line of sight (e.g., Kinney et al. 1991), (iii) the “double-cone” morphology of the narrow emission line structures, interpreted as due to the torus shadowing the central ionizing photons (Schmitt et al. 2003; Ruiz et al. 2005) and (iv) the similarity of the circumnuclear environments (Pogge & Martini 2002) and the luminosities of the molecular gas in Sy 1s and 2s (Curran et al. 2001). The universal validity of the Unification Scheme is still open to debate, however, with some results inconsistent with it, including (i) Sy 1 host galaxies being of earlier Hubble-type than Sy 2s (Malkan et al. 1998) and (ii) the galaxy densities around Sy 1s and 2s being dissimilar (Dultzin-Hacyan et al. 1999).

In the context of the Unified Scheme, we aimed to compare the hot gaseous outflows in Seyferts of the purportedly pole-on and edge-on kinds, as manifested in the $\text{OVI} \lambda\lambda 1032,1038$ emission line doublet along with any absorption that might be associated with it. This is possible using FUSE (the Far-Ultraviolet Spectroscopic Explorer: Moos et al. 2000; Sahnow et al. 2000) that can observe these wavelengths with spectral resolution $\lambda/\Delta\lambda$ of up to $\sim 20,000$. In the framework of unification, we can interpret any similarities and differences in terms of the geometry and viewing angle.

Here we present the results from our first observations, which were of Mrk 533 (NGC 7674), a Seyfert 2 at a redshift of 0.0289. It is the brightest galaxy in the gravitationally interacting compact group Hickson 96 (Verdes-Montenegro et al. 1997), and has its host galaxy oriented close to face-on
with the ratio of major to minor axes of $\sim 0.91$ (RC3: de Vaucouleurs et al. 1995). Mrk 533 has radio jets on the 100-pc scale (Momjian et al. 2003). Spectropolarimetric observations (Miller & Goodrich 1990; Tran 1995) have revealed a broad (FWHM $\sim 2830$ km s$^{-1}$) H$\beta$ line in polarized light, suggesting the presence of a genuine broad line region hidden by obscuring material in our line of sight. Mrk 533 has its optical continuum polarized (probably due to dust scattering) at a PA perpendicular to its radio axis (Tran 1995). It also shows evidence for Compton-thick X-ray emission and a reflection-dominated hard X-ray spectrum (Malaguti et al. 1998). Further, it shows H I absorption in the nuclear region (Beswick et al. 2002), and has been long known to have a spectacular blue-wing to its [O III]$\lambda 5007$ profile (e.g., Afanasev et al. 1980; Unger et al. 1988). The physical conditions of its narrow-line region were modeled from optical and IUE spectra by Kraemer et al. (1994).

We assume a Hubble constant of 75 km s$^{-1}$ Mpc$^{-1}$ which gives a scale of 541pc/arcsec.

2. THE OBSERVATIONS AND DATA REDUCTIONS

Mrk 533 was observed with the twin Rowland-circle spectrographs on FUSE during two separate pointings, on 2002 August 18 for 10,478s and on 2002 August 20 for 10,851s. The spectra were taken through the largest aperture, which has a size 30$''$×30$''$ (the “LWRS”). The ultraviolet photons are detected on micro-channel plate detectors, simultaneously via four independent optical channels, each of bandwidth $\sim 200\AA$. Two of these channels use Al+LiF coatings on the optics and the other two use SiC coatings (cf., Sahnow et al. 2000). The Mrk 533 data were recorded in a total of 10 exposures, in photon-counting “time-tag” mode. Due to astigmatic effects on the spectra, no reliable spatial information in the cross-dispersion direction can be obtained. The final spectral resolution is primarily constrained by the drifts of the object within the aperture. Only one of the channels, viz., the LiF1A, is continuously aligned on target by the guiding camera (the Fine Error Sensor), whereas the alignment with the rest of the channels is done on orbital time-scales.

Mrk 533 was also observed by HST STIS on 2000 September 12. The 52$''$×0.2$''$slit was centered on the peak of the stellar continuum and oriented at a position angle (PA) of 124$^\circ$, chosen to lie close to the two slightly different radio axes seen in the 15 GHz image of Unger et al. (1988). We present data obtained with an 1140 sec exposure using the G430M grating which gives a coverage of 280$\AA$ centered on a wavelength of 5095$\AA$ and sampled at 0.276$\AA$/pixel (FWHM= 2.5 pixels). The spatial scale is 0$''$.05/pixel.

2.1. The Pipelined Data from FUSE

Pre-processed data from the FUSE pipeline (CALFUSE version 3.1.0, Dixon et al. 2002) were used for this work. This pipeline-processing included (a) removing the effects of the thermally induced drifts of the target image on the detector via modelling; (b) flat-fielding using the pre-
launch two-dimensional flat field and the one-dimensional on-orbit flat field obtained by observing FUV-bright dwarfs; (c) conversion of wavelengths to the heliocentric reference frame and their calibration; (d) averaging the two-dimensional spectral image in the cross-dispersion direction to give a one-dimensional spectrum.

The relative motion of the spectrum on the detectors on an orbital time-scale results in shifting of the zero-point of the wavelength scale on the detector. From interstellar features, we found that these changes were $\leq 0.15 \, \text{Å}$, which at the observed wavelength of the O VI line corresponds to $\leq 45 \, \text{km s}^{-1}$.

2.2. The Co-added FUSE Spectrum

Data from all the 10 exposures in each of the channels were co-added. Because of their low effective area and the low signal, the data from the SiC channels were not usable, and therefore we only used data from the LiF1 and LiF2 channels. Their effective area amounts to $\sim 26 \, \text{cm}^2$. Photons from each of these channels are imaged by the optics onto two segments of the detector, labelled A and B. Thus the LiF1A and LiF2B data have overlapping coverage of the $\sim 1000–1090 \, \text{Å}$ region and the LiF2A and LiF1B data both cover the $\sim 1090–1190 \, \text{Å}$ region. A comparison of the count-rates with time in the LiF2 indicates that relative to the LiF1 channel there is no significant systematic loss of signal in it, and therefore no significant misalignment of the channels has occurred during the exposures. The signal in the two LiF channels is comparable and they were combined to form a single mean spectrum.

The co-added data were averaged along the cross-dispersion direction to obtain a one-dimensional spectrum. The pixels were binned along the dispersion direction by a factor of 8 to $\sim 0.05 \, \text{Å}$ per bin.

2.3. Derivation of the FUSE Background

The FUSE background is due to intrinsic detector background, the detector environment and scattered light. We did not use the background subtraction from the CALFUSE pipeline, since the pipeline extractions gave negative flux values for our data which indicates oversubtraction of the background. Instead, we used an empirical subtraction procedure of Murthy & Sahnow (2004) which uses the neighbourhood pixels next to the spectrum.

The procedure assumes that the value of the instrumental background within the aperture is identical to the value just off the aperture. The raw FUSE data were processed through the CALFUSE pipeline with the background-subtraction turned off. The resultant co-added 2-D data from each of the two exposures were then used. Data on either side of the desired aperture were averaged in the cross-dispersion direction and smoothed by a box-average in the dispersion direction.
to obtain the background spectrum. Although this procedure results in some smoothing of any wavelength-dependence of the background, it is clearly more representative, and moreover, gives flux values that lie above zero. We note that the spectral dependence of the background does not vary between orbital day and orbital night. Therefore the subtraction was done without separating the orbital day- and night-data. Further, within the noise, the background-subtracted data are consistent between the two different FUSE exposures, and also between the two LiF detectors with overlapping wavelength coverage, which vindicates our procedure.

2.4. Contamination of the FUSE Spectrum by Galactic Molecular H₂

As expected, the largest contaminant of the AGN spectra in the FUSE band is absorption by molecular H₂ in our Galaxy. We take this contamination into account by comparing the dips in our observed spectra with simple models of absorption by molecular hydrogen at zero redshift (Fullerton 2001). The H₂ absorption models are characterized by a single component at a kinetic temperature of 300 K, with zero metallicity, the rotational states chosen, a fixed atomic Hydrogen column density of $5.0 \times 10^{20} \text{cm}^{-2}$ and a varying molecular Hydrogen column density. More details are discussed in section 3.

2.5. Reduction of the HST STIS Data

The HST STIS data were calibrated within CALSTIS and cleaned using IRAF/COSMICRAYS. The slit location was verified by comparing the integrated flux with WFPC2 observations taken at similar wavelengths.

We note that the position of the STIS slit along the wavelength axis cannot be determined with the precision we need in order to calibrate the zero point of the wavelength scale. We therefore use the results from the data of Unger et al. (1988) taken with the IDS on the Isaac-Newton Telescope for this calibration. In their spectra, the wavelength of the peak of the [O III]λ5007 emission, and of the highly blueshifted component are 5153.0Å and 5134.6Å respectively, whereas the STIS data with CALSTIS calibration give 5155.4Å and 5137.1Å respectively, implying an offset between the STIS and ground-based data of +2.4Å and +2.5Å respectively. We therefore applied a shift of −2.5Å to the STIS data after calibration with CALSTIS.

3. THE EMISSION LINES IN THE INTRINSIC FAR-UV SPECTRUM OF MRK 533

The only strong line feature detected is the O VI doublet (Fig. 1). The C III emission at 977Å is seen weakly at its expected redshifted position (Fig. 3). We do not detect the Lyβ λ1026,
the He II $\lambda 1085$ or the Ne III $\lambda 991$ lines that were seen e.g., in the HUT spectrum of the archetypal Sy 2, NGC 1068 (Kriss et al. 1992). They would have been seen clearly at the equivalent widths observed in NGC 1068, as the continuum signal level in Mrk 533 in those wavelength regions are comparable to that near the O VI doublet.

Also plotted in Fig.1 is a model used for absorption by molecular hydrogen. The corresponding H$_2$ column density is $5 \times 10^{19}$ cm$^{-2}$, although we note that this model is not a unique one corresponding to this column density. An inspection of the dips in the model and comparison of their widths with the dips in the observed spectra clearly indicate that there is a correspondence between the strongest H$_2$ absorptions (marked in Fig. 1) and some of the dips in the observed spectra. The comparison model was chosen by inspection to have widths of the strongest absorptions comparable to those seen in the observed spectrum. The widths of the main absorptions in the region depend significantly on the column density. The data are consistent with the observed dips being due to the strongest H$_2$ absorptions with a shift of $-0.15\,\AA$. This is within the uncertainty in the calibration of the wavelength zero point of the FUSE spectrum.

Fig. 2 we show the profiles of the O VI doublet lines in velocity space. There is a small slope to the continuum around the O VI lines in the range 1050-1075\,\AA\ that rises with wavelength (Fig. 1). This slope is likely to be real and is also present in the archival spectrum that uses the FUSE pipeline background subtraction. We discuss possible extinction effects later. As we are concerned here with the emission line profiles, in plotting Fig. 2 we have simply subtracted the slope in the continuum across the O VI emission lines, by subtracting a linear continuum using the points at 1057–1058\,\AA\ and 1071–1073\,\AA\ . The diagrams show a level continuum at $4 \times 10^{-15}$ ergs cm$^{-2}$ s$^{-1}$ ang$^{-1}$.

The heliocentric systemic velocity of 8659 km s$^{-1}$ (see 5.2) was adopted for the velocity zero of the plot. The shift between the profiles of 5.85\,\AA\ is the separation of the OVI doublet redshifted by 0.02888. Apart from the removal of the linear slope, no other scaling was done.

Clearly the two profiles match within the noise except for a few troughs which in fact correspond to those in the illustrated H$_2$ absorption model. We show in Fig. 2 the result of a rough removal of this assumed contamination, estimated by comparing with the model H$_2$ spectrum. The heavy solid and light solid curves represent the 1032\,\AA\ and 1038\,\AA\ lines respectively. All the dips in each of the observed profiles that are assumed to be due to contaminating Galactic H$_2$ absorption are shown as dotted. In the case of each removal, the straight line compares well with the profile of the other line in that velocity region within the noise. The removals are also indicated in Fig. 1.

Given the good match of the profiles of the O VI doublet, they were combined to form a mean, plotted in Fig. 2. The profiles show an asymmetry about zero velocity in the form of an extension toward shorter wavelengths. Two possible dips remain in the average profile, corresponding to velocities of $-300$ km s$^{-1}$ and $-800$ km s$^{-1}$.

The spectrum of the C III $\lambda 977$ line (c.f., Fig. 3) is rather noisy, and apart from its detection, no definitive statement can be made about its profile. While it is interesting that data from both
the LiF channels show a relatively deep dip in a region that is clear of any H\textsubscript{2} absorption and corresponds to a velocity of $\sim -200\text{km s}^{-1}$, we consider this to be of only marginal significance in view of the low $S/N$.

Fig. 1.— The O\textsc{vi} doublet region of the spectrum of Mrk 533. Data from the detectors LiF1A & LiF2B which give redundant coverage of this region, have been combined (lower panel). On top in this panel an example of a model absorption spectrum of Galactic H\textsubscript{2} at zero redshift that corresponds to a H\textsubscript{2} column density of $5 \times 10^{19}\text{cm}^{-2}$ is illustrated (cf., 2.4), showing that several of the dips in the Mrk 533 spectra are contamination from absorption in our Galaxy. The positions of these troughs are indicated by horizontal lines above the upper H\textsubscript{2} spectrum. The dashed lines marked on the O\textsc{vi} spectrum indicate a rough removal of the effects of this absorption (cf., Sec. 3).

4. THE [O\textsc{iii}]\textsc{$\lambda$}5007 VELOCITY STRUCTURE OF Mrk 533 FROM HST STIS

In Fig.4, the HST STIS spectral image in the rest-frame [O\textsc{iii}]\textsc{$\lambda$}5007 spectral region is plotted in velocity space. The vertical axis is in the direction of the STIS slit which was oriented parallel to the radio axis (PA = 124\textdegree). The spatial zero point on this axis is the nominal nuclear position, taken to be the peak in the continuum. (It is possible that the true nucleus is shifted w.r.t. this position since the obscuring dust in the line of sight would be expected to attenuate its emission, thereby effectively shifting the continuum peak.) The zero position on the horizontal dispersion axis corresponds to the heliocentric systemic velocity.
Fig. 2.— The Mrk 533 spectra in the O VI region plotted in velocity space. A systemic redshift of 0.02888 (heliocentric velocity of 8659 km s\(^{-1}\)) and a doublet separation of 5.85 Å has been assumed. In the lower plot the heavy and light solid lines represent the spectra of the 1032 Å and 1038 Å lines respectively. The dotted curves represent the dips in these spectra that are assumed to be due to H\(_2\) absorption, and the corresponding solid lines show their rough removal (see 3 for further details). The averaged profile is plotted in the top panel along with a symmetrical (Gaussian) profile for comparison, which illustrates the shortward asymmetry of the observed profiles, as well as the suggestive residual absorption troughs at \(\sim-300\) km s\(^{-1}\) and \(-800\) km s\(^{-1}\). If real, these troughs could be intrinsic to Mrk 533.

Clearly, the [O III]λ5007 emission is spatially asymmetric, with most of the emission to the NW of the nominal nuclear position, along the radio axis (see images in Unger et al. 1988; Momjian et al. 2003). On the continuum peak, the [O III]λ5007 profile peaks close to the systemic velocity, and has a “blue shoulder” at \(\sim-100\) km s\(^{-1}\) (similar to what was reported earlier by Unger et al. 1988; Veilleux 1991b). Roughly 0'.1 to the NW, the peak shifts to \(\sim+200\) km s\(^{-1}\) while there is a broad blueshifted peak at \(\sim-1000\) km s\(^{-1}\) with an extended wing reaching \(\sim-2000\) km s\(^{-1}\). The spatial extent of this broad maximum appears to be 0 – 0'.2.

5. DISCUSSION

We assume in our analysis that all the spectral emission in the FUSE data is attributable to the AGN and its photoionization effects, and that even in the 30''×30'' aperture, the contribution
Fig. 3.— The spectrum in the C III region plotted in velocity space. The S/N is much lower in this region, but nevertheless the C III emission is detected. The model H2 absorption spectrum at zero redshift is plotted on top. A symmetrical (Gaussian) profile is plotted to guide the eye, but no attempt has been made to remove the effect of Galactic H2 absorption. A trough is seen (in both detectors, combined here) in a region that is clear of Galactic H2 absorption, which corresponds to a velocity of $-200\text{km s}^{-1}$, but is at best of marginal significance.

from hot stars is negligible. This assumption is supported by a comparison of the Mrk 533 spectrum with the FUSE spectra from hot stars in the atlas of Walborn et al. (2002). None of the expected strong emission lines from stars is seen in our spectra, so we assume that all emission arises in the AGN.

We also recall that in e.g., NGC 3516, Hutchings et al. (2001) find from a comparison of contemporaneous large-aperture FUSE spectra and narrower-aperture HST STIS spectra that the continuum levels in the overlapping spectral region match very well. They conclude therefore, albeit for a Sy 1, that the continuum is dominated by nuclear emission and there is no significant contribution to the FUSE photons from starlight at larger radii.
Fig. 4.— The *HST STIS* spectral image of Mrk 533 in the region of [O III]λ5007 line is plotted in velocity space. The vertical spatial axis is along the *STIS* slit at a PA of 124° (along the radio axis). The zero position of this axis corresponds to the peak of the continuum in the off-line region. The zero position of the horizontal dispersion axis corresponds to the systemic velocity of 8659 km s\(^{-1}\) (cf., Sec. 4).

### 5.1. The Line-Ratio of the O VI Doublet

The statistical weights of the upper levels of the O VI doublet transitions are two and four for the longward and shortward wavelength lines respectively, implying an intensity ratio of two for the doublet under the assumptions that the emission is optically thin and that the emitters are in LTE (Mauche & Raymond 1998). In the Sy 1s, this is indeed the typical ratio that has been found for the broad emission-line region (Kriss, private communication).

In Mrk 533, however, the two doublet lines of the O VI emission match very well in both intensity and profile as can be seen from Fig. 2. We estimate the line flux in both cases to be \(\sim 3.7(\pm 0.2) \times 10^{-14} \text{ ergs s}^{-1} \text{ cm}^{-2}\). Thus the doublet ratio is \(\sim 1\), similar to the value inferred from *HUT* data for NGC 1068 by Kriss et al. (1992) and in contrast to the trend seen in Sy 1s. This means that the O VI line is optically thick over roughly the whole velocity range in Mrk 533. These
aspects are being investigated in detail in a subsequent paper (P. Shastri et al. in preparation).

We note that the effect of the rising slope of the continuum in the wavelength range 1055-1075˚A (cf., Sec. 3) has been taken out in plotting Fig. 2 and thus it clearly does not alter our conclusion about line ratio of the doublet.

5.2. Shifts of the Lines Relative to Systemic

We use a heliocentric systemic velocity \( cz = 8659 \text{ km s}^{-1} \), which is the mean of the host galaxy stellar velocity from Nelson & Whittle (1995) and the values derived by Unger et al. (1988) and Nishiura et al. (2000) from their \( \text{H}\alpha \) rotation curves. The corresponding heliocentric redshift is 0.02888.

Within the spectral resolution constraint of the \textit{FUSE} data, the recession velocities derived from the peaks of the \( \text{O\ VI} \) doublet and the \( \text{C\ III} \) line are consistent with the systemic velocity. Right at the nominal nuclear position, the \([\text{O\ III}]\lambda5007\) peak is also at systemic (Fig. 4), though a larger aperture would find the strongest near-nuclear \([\text{O\ III}]\lambda5007\) emission to be redshifted by \( \sim 200\text{km s}^{-1} \). This shift relative to systemic was noted from ground based spectra by Unger et al. (1988, \([\text{O\ III}]\lambda5007\) ) and Nelson & Whittle (1995, \([\text{S\ III}]\lambda9069\) ). It is likely that such spatial and velocity structure accounts for other small redshift differences noted in the literature, such as the peak \( \text{H}\alpha \) of 8756 km s\(^{-1}\) measured by Veilleux (1991a). Two other velocities deserve mention. The \( \text{CO} \) emission is centered essentially at systemic (8669 km s\(^{-1}\), Sanders & Mirabel 1985), as one might expect for dense gas relatively deep in the galaxy potential. Finally, \( \text{H}\ I \) is seen in slightly blueshifted absorption (8623 km s\(^{-1}\), Beswick et al. 2002) consistent with a modest outflow on \( \sim 100\text{ pc scales} \). Tidal interactions with the other galaxies of the compact group (Verdes-Montenegro et al. 1997) can also create shifts in the overall peak of the neutral gas.

5.3. Intrinsic Absorption by Molecular Hydrogen

We do not find any \( \text{H}_2 \) absorption that is intrinsic to Mrk 533 (\textit{e.g.}, from the putative torus, given that it is a Sy 2). Indeed, since the nuclear continuum emission is expected to be attenuated due to obscuration, it is not surprising that it is too weak to measure any absorption against it.

5.4. Absorption in the Outflow?

Strong absorptions in the profile of the \textit{FUV} emission lines are a characteristic feature of the Seyfert 1 galaxies observed by \textit{FUSE} (\textit{e.g.}, Kriss 2005). In the case of Mrk 533, however, the evidence for absorption is less definitive. This is not entirely surprising for a Sy 2, given that the nuclear continuum is expected to be significantly attenuated, and the outflow is expected to be
primarily along the AGN axis, and obscured in the near-nuclear region.

The combined profile in Fig. 2 shows two dips in both lines of the O\textsc{vi} doublet, at $-300$ km s$^{-1}$ and $-800$ km s$^{-1}$ (see Fig. 2). These are residual dips that remain after accounting for absorption by Galactic H$_2$, and have no local identification. Their significance is not high, however, and better $\text{SN}$ data are required for any definitive interpretation. If real, they would have to be due to absorbers intrinsic to Mrk 533: It is possible that the absorption at $-300$ km s$^{-1}$ is associated with the outflow from the nucleus, but could also be from an interstellar cloud associated with the circumnuclear starburst that is known to be present in Mrk 533. The latter absorption (at $-800$ km s$^{-1}$) on the other hand has too large a velocity to be associated with such a starburst, which would imply that it would have to be due to a foreground cloud associated with the outflow.

In the case of the C\textsc{iii} emission line, our data are very noisy, and although there is a suggestion of a dip in both the photon channels in a region clear of any Galactic H$_2$ absorption which corresponds to a velocity of $-200$ km s$^{-1}$, this feature is at best of marginal significance.

5.5. The Line Profiles and their Blue-ward Asymmetry

The fact that the O\textsc{vi} emission lines are narrow (e.g., comparable to the width of the core of the [O \textsc{iii}]$\lambda5007$ line, see Fig. 5) is, of course, consistent with the basic classification of Mrk 533 as a Seyfert 2. In Seyfert 1s, the O\textsc{vi} lines are usually much broader although some have an additional narrow component (Kriss 2004).

Fig. 5 compares the O\textsc{vi} and [O \textsc{iii}]$\lambda5007$ emission profiles. The \textit{STIS} profiles in this plot were extracted using (a) a 'nuclear' aperture corresponding to one pixel row centered on the zero position, (b) an 'off-nuclear' aperture corresponding to pixel row $\sim 0''15$ to the NW relative to zero position, (c) the whole long-slit aperture. The combined profile of the two O\textsc{vi} doublet lines is also shown.

It has been long known that Mrk 533 has a spectacular blue-wing to its [O \textsc{iii}]$\lambda5007$, H$\beta$ and H$\alpha$ profiles and a less striking wing in the N$\text{ii}$ profile (e.g., Afanasev et al. 1980; Unger et al. 1988; Veilleux 1991a). A striking feature of the \textit{FUSE} profile of the O\textsc{vi} doublet is that it also shows an asymmetry in the same sense. However, it lacks the extended wing shortward of the peak wavelength seen in the the lower ionization lines to $-2000$ km s$^{-1}$, and its peak also appears centered near the systemic velocity, unlike the long-slit (large aperture) [O \textsc{iii}]$\lambda5007$ profile (top panel, Fig. 5). de Robertis & Shaw (1990) had earlier shown that the asymmetry of the emission lines correlate with the ionization potential, for several Seyferts including Mrk 533, but its O\textsc{vi} line clearly does not fit this correlation.

Before concluding that the differences between the profiles of the [O \textsc{iii}]$\lambda5007$ and O\textsc{vi} lines are real, we must consider the impact of different aperture sizes on the profile shapes. In fact, the large size of the \textit{FUSE} aperture introduces two potential concerns. The first is that ex-
tended O VI emission might be included. However, the low excitation measured outside the nucleus (e.g., \([\text{OIII}]/H_\beta < 0.5\), Unger et al. 1988) suggests there will be little if any off-nuclear O VI contribution. Second, mis-centering the Mrk 533 nucleus in the aperture could lead to significant wavelength uncertainty. In our case, however, we used the values from the LiF1A (guiding) channel which guarantees good centering, and we have determined that the uncertainty is \(\leq 45\) km s\(^{-1}\) (cf., Sec 2.1). Hence, we conclude that the peak of the O VI emission is indeed centered on sytemic within the errors, and that it indeed lacks the very extended wing shortward of the peak that is seen in the total \([\text{O III}]\lambda 5007\) profile. This is in fact consistent with the O VI emission arising within 0.05 of the nucleus since this matches the narrower \([\text{O III}]\lambda 5007\) profile from this innermost region (cf., Fig. 5). Thus, although the long-slit aperture of the \([\text{O III}]\lambda 5007\) STIS observation (top panel, Fig. 5) resembles most closely the FUSE aperture in spatial scale, nevertheless, the O VI profile actually closely resembles in both shape and position w.r.t. systemic, the nuclear \([\text{O III}]\lambda 5007\) profile, which we know arises within \(\sim 0.05\) or \(\sim 30\)pc from the continuum source. This suggests that the O VI emission arises from this inner \(\sim 0.05\) region, similar to what has been conjectured for the narrow component to the O VI line in e.g., NGC 3516 (Hutchings et al. 2001). We also note that the similarity of the O VI and the nuclear \([\text{O III}]\lambda 5007\) profiles argue against complex extinction in this region.

Clearly, beyond 0.05 or \(\sim 30\)pc from the continuum peak, (and by implication, beyond at least this distance from the putative nucleus), the \([\text{O III}]\lambda 5007\) profile is dominated by the blue-wing. If there is corresponding redshifted emission from a receding part of the outflow, it must be hidden from view.

Of relevance here is the fact that the low-ionization lines of Mrk 533 (Veilleux 1991a) do show the extended blue-wings up to \(\sim -2000\) km s\(^{-1}\). The case of H\(\beta\) from our data is shown in Fig. 5. An archival HST FOS spectrum shows that the Mg II\(\lambda 2798\) line has a similar profile.

In this picture, the ionization parameter drops sufficiently quickly with distance from the nucleus so that the O VI line is no longer generated in the blue wing gas found \(\sim 0''.1 - 0''.2\) (50 – 100pc) off-nucleus. This off-nuclear gas, it would seem, has been accelerated either by a nuclear wind or the near-nuclear radio-emitting hotspot (seen, e.g., example, in the images of Momjian et al. (2003) which exhibits structures in approximately the same location). Evidence for accelerated flows on scales of 0.2 has been found in several Seyferts by Ruiz et al. (2005). It is perhaps relevant here that there is also direct evidence for acceleration in some Sy 1 galaxies (e.g., Hutchings et al. 2001; de Kool 1997), although on a somewhat smaller physical scale.

The blue wing is most commonly interpreted as arising from outflow of line-emitting gas with a distributed source of opacity (dust) which obscures the far side (e.g., Whittle 1985; Veilleux 1991b). The alternative – infalling dusty clouds emitting preferentially from the side facing the central source – seems unlikely in this case, not least because some of the highest velocity blueshifted gas is seen off-nucleus where we know the gravitational velocities are a factor 10 smaller. Fig. 4 shows that most of the \([\text{O III}]\lambda 5007\) emission comes from a region NW of the nucleus, which
Fig. 5.— The profiles of the [O III]λ5007 and Hβ lines from the HST STIS data are plotted together with the O VI profile from FUSE. In the top panel, the solid and dashed curves represent the profiles of the [O III]λ5007 and Hβ lines respectively, as extracted from a STIS long-slit aperture. In the middle panel, the solid curve represents the profile of the [O III]λ5007 line extracted from a ‘nuclear’ aperture (the 42nd pixel row in the STIS data which is at the continuum position). The dashed curve represents the profile from the off-nuclear region, ∼ 0″.15 NW from the ‘nucleus’ (pixel row 39). The y-scale in this panel is magnified by a factor of 3. The solid curve in the bottom panel is the O VI profile from the FUSE spectrum from Fig. 2, to compare and contrast with the STIS profile.

reinforces the idea that the [O III]λ5007 emission arises from an approaching outflow, the receding side of which is hidden. The torus in the line of sight could provide the opacity required to produce the blue wings, by obscuring the photons from the redshifted part of the profile, which would be those closest to the nucleus but moving away from us. It perhaps also contributes significantly to the obscuration of the [O III]λ5007 emission from the SE side of the nuclear region, making the [O III]λ5007 structure appear ‘one-sided’. It may be recalled that the host galaxy of Mrk 533 is oriented face-on, an unexceptional fact, given the lack of correlation between the host galaxy axis and the AGN axis in Seyferts (Schmitt et al. 2003).

Thus if the 'shoulders' shortward of the peak in both the [O III]λ5007 and O VI profiles originate
in the same gas, it means that the shortward asymmetry of the O VI emission results from a high excitation outflow within 0.’05 or ~30pc from the nucleus, and any corresponding redshifted emission from the receding part of the outflow is hidden from view.

Obscuration of the receding flow implies that dust is present and may affect what we see of the approaching flow too. The small rise in the continuum with wavelength implies some extinction of the nuclear continuum. The redshifted peak of the [O III]λ5007 line relative to systemic 0.’15 NW of the nucleus could be understood in this picture. Kraemer et al. (1994) quote a reddening value E(B-V)=0.20 based on the line flux ratios, but given the uncertainties in the extinction curve in the FUSE range, we are unable to quantitatively comment on the consistency of our continuum slope with this reddening value. Using our line fluxes for the O VI, and the Hβ line flux from Kraemer et al. (1994) the line ratio of $\frac{OVI}{H\beta}$ is $\sim 0.6$. Patchy dust could of course complicate all the profiles, and we would need much more detailed evidence to consider that. For now, we note particularly that the O VI profile is very similar to the nuclear [O III] profile. However, given the significant differences in the overall shapes of the O VI and off-nuclear [O III]λ5007 profiles even in regions where the $\frac{OIII}{H\beta}$ is high, it is very unlikely that such differences can arise from dust extinction, and therefore must be principally attributed to velocity and ionization gradients.

A further conclusion from the absence of an extended shortward wing in the O VI profile is that this high velocity gas is likely to be photoionized by the central source, rather than shock-ionized by a wind or jet. In the shock-ionization picture one would expect, at least naively, that the highest velocity gas would have the highest ionization. That this is not the case in Mrk 533 argues against shock ionization. A more detailed analysis using lower ionization lines gave a similar result for Mrk 78 (Whittle et al. 2005), but in the case of Mrk 533 the large difference in the degree of ionization between O $^{5+}$ and O $^{2+}$ makes for a stronger case.

Finally, we note that the picture described here is also consistent with the spectropolarimetric results of Tran (1995) who found that the [O III]λ5007 profile in polarized light was narrower and had no extended blue wing. The region producing the scattered light is likely to be highly nuclear (afterall, the polarized spectrum shows broad Hβ) and hence it is not surprising that the scattered [O III]λ5007 profile matches our most nuclear STIS data: narrower profile, centered on systemic, and with little blue wing; indeed similar to the O VI profile.

If the outflow is in the form of a hollow bi-cone (e.g., Ruiz et al. 2005), then, depending on the opening angle and the inclination of the line of sight, we may see both approaching and receding velocities along the line-of-sight from the approaching ‘cone’. The obscuring torus may then also affect the nuclear part of the emission profile from the approaching ‘cone’, and, e.g., preferentially obscure the approaching velocities. The redshifted peak of the [O III]λ5007 line relative to systemic could be understood in this picture, although we do not have enough spatial resolution to model it in detail.
6. CONCLUSIONS

We present high resolution FUSE spectra of the permitted ultraviolet O VI $\lambda\lambda$1032,1038 and C III $\lambda$977 lines and HST STIS spectra of the [O III]$\lambda$5007 optical line, of the Seyfert 2 galaxy Mrk 533 (NGC 7674). We find the following:

1. The O VI doublet lines are strong and relatively narrow, consistent with their origin in the narrow-line region. This is in predicted contrast to the very broad O VI line reported in Seyferts of type 1 which are purportedly pole-on.

2. The C III $\lambda$977 emission line is also weakly detected with similar line width, but the Ly\(\beta\) $\lambda$1026, He II $\lambda$1085 and Ne III $\lambda$991 emission lines are not detected.

3. The profiles of the two doublet lines of O VI emission are very well matched, implying a line ratio of $\sim 1$, and thus optically thick emission. This fact is also consistent with O VI doublet not originating in a broad-line region which typically shows a flux ratio $\sim 2$.

4. After correcting for Galactic H$_2$ absorption, we identify with somewhat marginal significance two possible intrinsic absorption features in the O VI profile at $-300$ km s$^{-1}$ and $-800$ km s$^{-1}$.

5. The O VI velocity profile is centered near the systemic velocity and has a moderate shortward asymmetry. This matches quite well the [O III]$\lambda$5007 profile from the innermost pixel ($<0''$.05, i.e., <30pc) of the STIS data.

6. However, moving only slightly off nucleus (0''.1–0''.2 or 50-100pc), the [O III]$\lambda$5007 profile peak shifts to $+100$ km s$^{-1}$ and the shortward side gains a strong wing extending to $\sim -2000$ km s$^{-1}$.

7. The difference between the O VI and [O III]$\lambda$5007 profiles is consistent with a picture in which the most nuclear region exhibits velocities $\sim 500$ km s$^{-1}$ in mild outflow with the receding part hidden from view. However, beyond this inner region, the gas is strongly accelerated by a nuclear wind or jet flow. The narrow and symmetric profile of the polarized [O III]$\lambda$5007 line is also consistent with this picture.

8. The absence of O VI emission in the highly accelerated [O III]$\lambda$5007 -emitting gas argues in support of this gas being photoionized rather than shock-ionized.

Help from the FUSE team during the proposal and observation stages, and the efforts that have gone into the high quality of their user services are gratefully acknowledged. We thank Suzy Collin for several insightful discussions, and the anonymous referee whose comments improved the paper very significantly. This paper is based on observations made with the NASA-CNES-CSA Far Ultraviolet Spectroscopic Explorer. FUSE is operated for NASA by the Johns Hopkins University under NASA contract NAS5-32985. The HST STIS spectra are based on observations obtained
at the Space Telescope Science Institute which is operated by the Association of Universities for Research in Astronomy, Inc., under NASA contract NAS 5-26555. Support for the HST proposal GO-8453 was provided by NASA through a grant from the Space Telescope Science Institute. The FUSE research was supported by NASA grant NAG5-13726. This research has made use of the Canadian Astronomy Data Centre (CADC), NASA’s Astrophysics Data System bibliographic services and the NASA/IPAC Extragalactic Database (NED) which is operated by the Jet Propulsion Laboratory, California Institute of Technology, under contract with NASA.
