In this talk, we describe part of a recent work [1] on the correlation function of a $V$−$A$ current with a $V$+ $A$ current in the framework of QCD in the limit of a large number of colours $N_c$. The discussion takes place within two successive approximations of this theory, called MHA and MHA+V’. Results concerning the evaluation of chiral condensates of dimension six and eight, as well as matrix elements of the $Q_7$ and $Q_8$ electroweak penguin operators, are given.

1. Introduction

The correlation function of a left–handed current with a right–handed current

$$L^\mu(x) = \bar{u}(x)\gamma^\mu\frac{1-\gamma_5}{2}d(x)$$

and

$$R^\nu(0) = \bar{d}(0)\gamma^\nu\frac{1+\gamma_5}{2}u(0),$$

in QCD and in the chiral limit, depends only on one invariant amplitude $\Pi_{LR}(Q^2)$ of the euclidean momentum squared $Q^2 = -q^2$, with $q$ the momentum flowing through the two–point function:

$$2i\int d^4xe^{iq\cdot x}\langle 0|T\{L^\mu(x) R^\nu(0)\}|0\rangle = (q^\mu q^\nu - q^2 g^{\mu\nu}) \Pi_{LR}(Q^2). (1)$$

Here, we shall be particularly concerned with the study of $\Pi_{LR}(Q^2)$ in the limit of a large number of colors $N_c$ in QCD. We want to compute the lowest dimension operator product expansion (OPE) condensates of this function in two successive approximations to the large–$N_c$ limit: the so-called minimal hadronic approximation (MHA) [2] consisting of a spectrum of the pion state, a vector state and an axial vector state; and the improved approximation where an extra higher vector state is added.

Part of our motivation comes from the fact that in the literature the values of these condensates are rather controversial. Phenomenological analyses in refs. [3,4,5] find for example opposite sign for the first two condensates, in contradistinction to the results in refs. [6,7,8] which find the same sign.

In this talk, we give results only for the two lowest dimension condensates and the matrix elements of $Q_7$ and $Q_8$ (see however [11] for more results and details).

In practice, we shall be working with the dimensionless complex function $W_{LR}[z]$ defined as

$$W_{LR}[z] = -z\Pi_{LR}(z M_\rho^2), \quad \text{with} \quad \Re z = \frac{Q^2}{M_\rho^2},$$

and use the mass of the lowest massive state, the $\rho(770 \text{ MeV})$, to normalize quantities with dimensions. In large–$N_c$ QCD the function $W_{LR}[z]$ is a meromorphic function and, therefore, in full generality, it can be approximated by successive par-
tial fractions of the type
\[ W_{LR}[z] = A_N \prod_{i=1}^{P} \frac{1}{(z + \rho_i)} \prod_{j=1}^{N} (z + \sigma_j), \]  
with \( \rho_1 = 1 \) and \( \rho_i \neq \rho_k \) for \( i \neq k \); where \( P \) (and \( N \)) get larger and larger, but finite. \( A_N \) is the overall normalization and in what follows, we shall often use the notation \( \rho_2 \equiv \rho_A \) and \( \rho_3 \equiv \rho_{V'} \).

On the other hand, in QCD, the OPE of the two currents in Eq. (1) fixes the large–Q\( ^2 \) fall off in 1/Q\( ^2 \)-powers of the invariant function \( \Pi_{LR}(Q^2) \) to

\[ \Pi_{LR}(Q^2) \equiv \sum_{n=1}^{\infty} c_{2n+4}(Q^2, \mu^2) \times \langle O_{2n+4}(\mu^2) \rangle (Q^2)^{-(n+2)} = 1 + \frac{2}{\sigma} \sum_{n=1}^{\infty} \langle O_{2n+4} \rangle (Q^2)^{n+2}. \]  

Matching the leading asymptotic behaviour for large–z in Eq. (4) to the one of the OPE in Eq. (3), restricts the number of zeros \( N \) and the number of poles \( P \) in Eq. (4) to obey the constraint

\[ N - P = -2. \]  
The case where \( N = 0 \) corresponds to the MHA while the MHA+V' case is obtained for \( N = 1 \).

2. \( \Pi_{LR} \) in the MHA and \( \pi - V - A - V' \) Spectra

It is claimed by some of the authors of refs. [6, 7, 8] that the reason why their phenomenological analysis of the chiral condensates give the same sign for \( \langle O_6 \rangle \) and \( \langle O_8 \rangle \) is due to the fact that the hadronic \( \tau \)-decay spectrum is sensitive to the presence of the \( \rho' \), while the MHA ignores all higher states beyond the first axial state. Partly motivated by this claim, we want to analyze here the case, beyond the MHA, where an extra vector state \( V' \), and therefore one zero \( \sigma \), are also included. Let us collect some relevant equations describing this case (the corresponding expressions in the MHA case can be obtained by putting \( \rho_{V'} = \sigma \) in the MHA+V' equations).

2.1. The Correlation Function

With a spectrum of the pion pole, and \( V, A \), and \( V' \) states, the relevant correlation function is

\[ W_{LR}[z] = A_1 \frac{z + \sigma}{(z + 1)(z + \rho_A)(z + \rho_{V'})}, \]  
where \( A_1 \equiv \frac{\sigma}{\rho_A \rho_{V'}} \equiv \rho_F \) and therefore

\[ \langle O_6 \rangle = -\frac{2}{\sigma} F_0^2 M_A^2 M_{V'}^2 = -M_{V'}^2 \frac{2}{\sigma} \rho_F \rho_A \rho_{V'}. \]  

Because of the positivity of \( W_{LR}[z] \) for Re \( z \geq 0 \), the position of the zero has to be in the Minkowski axis and, then, \( \sigma > 0 \).

2.2. The Linear Constraint

This is a very interesting constraint, key equation of our analysis, which already provides a semi-quantitative argument in favor of the opposite sign option for the condensates \( \langle O_6 \rangle \) and \( \langle O_8 \rangle \). It simply follows by expanding Eq. (2) to first non–trivial order in inverse powers of \( z \)

\[ \sum_{j=1}^{N} \sigma_j - \sum_{i=1}^{P} \rho_i = \frac{1}{M_{V'}^2} \frac{\langle O_8 \rangle}{\langle O_6 \rangle}. \]  

In the case corresponding to the MHA, where by definition there are no zeros, this constraint simply becomes:

\[ 1 + \rho_A = -\frac{1}{M_{V'}^2} \frac{\langle O_8 \rangle}{\langle O_6 \rangle}, \]  

implying that, in the MHA \( \langle O_8 \rangle \) and \( \langle O_6 \rangle \) must have opposite signs.

Now, in the MHA+V' case, Eq. (6) reduces to

\[ \sigma - (1 + \rho_A + \rho_{V'}) = \frac{1}{M_{V'}^2} \frac{\langle O_8 \rangle}{\langle O_6 \rangle}. \]  

This equation states that for \( \langle O_8 \rangle \) to have the same sign as \( \langle O_6 \rangle \), the position of the zero has to be far beyond the largest \( V' \)-pole:

\[ \sigma > 1 + \rho_A + \rho_{V'}. \]  

Fixing the position of the poles at the values of the observed spectrum (and ignoring errors for
the purpose of the discussion), one has \( M_V = 0.776 \) GeV, \( M_A = 1.230 \) GeV (\( \rho_A = 2.5 \)) and \( M_{V'} = 1.465 \) GeV (\( \rho_{V'} = 3.6 \)); which means that for the equal sign requirement option to be satisfied, one must have \( \sigma > 7.2 \). In GeV units this corresponds to a mass of 2.1 GeV. Now, in writing a large–\( N_c \) ansatz for the \( W_{L,R}[z] \) function, one is implicitly assuming an effective cancellation between the extra poles and zeros in the complex \( z \)–plane which lie beyond a disc of radius \( s_0 \) covering all the poles and zeros retained in that approximation. The result \( \sigma > 7.2 \) implies that the radius in question has to be \( \sqrt{s_0} > 2.1 \) GeV.

A priori that seems a good thing because the OPE–matching is now applied at \( Q^2 \geq s_0 \); i.e. in a more asymptotic region than in the case of the MHA ansatz; however, it also implies that there are no further poles in the region between \( M_{V''} \approx 1.5 \) and the effective mass \( M_\sigma \approx 2.1 \) GeV corresponding to the zero at \( \sigma \approx 7.2 \). This, however, is in contradiction with the observed \( a_1 \)–like state at \( M_\rho \approx 1.64 \) GeV and \( \rho \)–like states at \( M_{V''} \approx 1.72 \) GeV and \( M_{V''''} \approx 1.9 \) GeV below \( M_\sigma \approx 2.1 \) GeV. Alternatively, if one excludes those three states \( A', V'' \) and \( V''' \) as all the phenomenological analyses using \( \pi \)–data do in fact, then the position of the zero \( \sigma \) should be \( \sigma \approx \frac{M_\rho^2}{M_\sigma^2} \approx 4.5 \), implying according to Eq. (9), that \( \langle Q_8 \rangle \) and \( \langle Q_6 \rangle \) must have opposite signs, in contradiction with the claims of refs. [7,8].

3. Numerical Analyses and Conclusions

Confronting the MHA and MHA+V’ approximations to the experimental values of some observables that we introduce in the following will allow us to test their consistency and adjust their free parameters (\( \rho_F \) and \( \rho_A \) in the MHA case, \( \rho_F, \rho_A, \rho_{V'}, \sigma \) in the MHA+V’ case) in order to make predictions for the condensates and matrix elements. We use as input the following set of experimental data

\[
\begin{align*}
\delta m_\pi &= 4.5936 \pm 0.0005 \text{ MeV}, \quad \text{ref. [1]} \\
L_{10} &= (-5.13 \pm 0.19) \times 10^{-3}, \quad \text{ref. [2]} \\
\Gamma_{\rho \rightarrow \pi^+ \pi^-} &= (6.77 \pm 0.32) \times 10^{-3} \text{ MeV}, \quad \text{ref. [1]} \\
\Gamma_{a \rightarrow \pi \gamma} &= (640 \pm 246) \times 10^{-3} \text{ MeV}, \quad \text{ref. [1]} \\
L_9 &= (6.9 \pm 0.7) \times 10^{-3}, \quad \text{ref. [1]} \\
M_\rho &= (775.9 \pm 0.5) \text{ MeV}; \quad \text{ref. [1]} \\
\end{align*}
\]

In fact, some of these observables, when expressed in terms of the MHA or MHA+V’ parameters, depend not only on these ones but also on \( (m_{\pi^0} + m_{\pi^+}) \) and/or \( M_{V'} \). Therefore, it is more appropriate for our purposes to use in our fit procedure the dimensionless quantities:

\[
\begin{align*}
\frac{m_{\pi^+} + m_{\pi^0}}{M_\rho^2} \delta m_\pi &= \frac{3 \alpha \rho_A \log(\rho_A)}{4 \pi \rho_A - 1}, \quad (10) \\
L_{10} &= \frac{1}{4} \rho_F \left( \frac{1 + \frac{1}{\rho_A}}{\rho_A} \right), \quad (11) \\
\frac{1}{M_\rho} \Gamma_{\rho \rightarrow \pi^+ \pi^-} &= \frac{4 \pi \alpha^2}{3} \frac{\rho_A}{\rho_A - 1}, \quad (12) \\
\frac{1}{M_\rho} \Gamma_{a \rightarrow \pi \gamma} &= \frac{\alpha}{24 \rho_A} \sqrt{\rho_A - 1}, \quad (13) \\
L_9 &= \frac{1}{2} \rho_F. \quad (14)
\end{align*}
\]

For lack of place we gave the formulae only in the case of the MHA, the corresponding MHA+V’ equations can be found in [1].

A standard \( \chi^2 \) statistical regression method permits to fit the parameters.

3.1. The case of the MHA spectrum

For this spectrum, we find \( \rho_F = (12.36 \pm 0.35) \times 10^{-3} \) and \( \rho_A = 1.464 \pm 0.004 \), with a \( \chi^2_{\text{min}} = 1.21 \) for 3 degrees of freedom (dof). The covariance matrix is given by

\[
\text{cov} (\rho_F, \rho_A) = \begin{pmatrix} 1.21 & 1.36 \\ 1.36 & 162 \end{pmatrix} \times 10^{-7}. \quad (15)
\]

We deduce from these results two conclusions: first that the MHA framework is statistically relevant and second that the fitted free parameters have small statistical errors.

3.2. The case of a \( \pi - V - A - V' \) spectrum

Eq. (14) becomes now a function of \( g_{V'} \) as explained in [1]. The way we treat this is by con-
sidering the observable:\(^2\):

\[
\frac{1}{M_\rho} \Gamma_{\rho \to \pi \pi} = \frac{1}{48\pi} \times \frac{1}{\rho_F} \left( \frac{(\rho_F - 2L_0\rho_{\nu'})^2 (\rho_A - 1)(\rho_{\nu'} - 1)}{(1 - \rho_{\nu'})^2 \rho_F \rho_A \rho_{\nu'}(\sigma - 1)} \right),
\]

as a function of \(L_0\) which has an error itself, and is added as an extra parameter in our fit. The number of dof does not change since \(L_0\) is also taken as an observable. For this case, we impose a criterion of rejection through the ordering:

\[
\rho_A < \rho_{\nu'} < \sigma < \rho_0 \approx \frac{s_0}{M_V^2}.
\]

The first and second inequalities reflect the knowledge that the new state has a higher mass than the axial, that it is a \(V\)–like pole and, therefore, its residue contributes positively to the \(W_{LR}(z)\)–function; the third inequality follows from the requirement that the perturbative threshold \(s_0\) already lies beyond the radius where the analytic structure of the poles and zeros retained satisfies the leading OPE constraint.

The \(\chi^2\) regression leads to

\[
\begin{align*}
\rho_F &= (12.36 \pm 0.03) \times 10^{-3}, \\
\rho_A &= 1.466 \pm 0.003, \\
\rho_{\nu'} &= 2.63 \pm 0.01, \\
\sigma &= 2.64 \pm 0.01.
\end{align*}
\]

The results in Eqs. (16) to (19) correspond to a value: \(L_0 = (6.44 \pm 0.02) \times 10^{-3}\), with a \(\chi^2_{\text{min}} = 0.60\) for 1 dof.

We conclude that the parameters \(\rho_F\) and \(\rho_A\) are statistically stable when compared to those found in the MHA case. We also find that \(\rho_{\nu'} \approx \sigma\), which is consistent with the fact that the MHA approximation already seems to have the bulk of the full large–\(N_c\) information. In other words, adding an extra \(V'\)–pole appears to be compensated, at a very good approximation, by the position of the nearby zero.

### 3.3. predictions

Using Eqs. (5), (8) (and corresponding equations in the MHA case) as well as expressions of the matrix elements of four-quark operators (11, 12), we find

| \(\mathcal{O}_6\) | \(\mathcal{O}_8\) |
|---|---|
| \(\text{MHA + V'}\) | \(-7.90 \pm 0.20 \pm 1.62\) | \(+11.69 \pm 0.32 \pm 2.53\) |
| \(\text{MHA}\) | \(-7.89 \pm 0.23 \pm 2.01\) | \(+11.71 \pm 0.34 \pm 3.08\) |

The way of obtention of these results as well as the origin of systematic errors are explained in [11].

We then see that within errors, the two sets of predictions from MHA and from MHA + \(V'\) are perfectly consistent with each other.
