Abstract
Hate speech and toxic comments are a common concern of social media platform users. Although these comments are, fortunately, the minority in these platforms, they are still capable of causing harm. Therefore, identifying these comments is an important task for studying and preventing the proliferation of toxicity in social media. Previous work in automatically detecting toxic comments focus mainly in English, with very few work in languages like Brazilian Portuguese. In this paper, we propose a new large-scale dataset for Brazilian Portuguese with tweets annotated as either toxic or non-toxic or in different types of toxicity. We present our dataset collection and annotation process, where we aimed to select candidates covering multiple demographic groups. State-of-the-art BERT models were able to achieve 76% macro-$F_1$ score using monolingual data in the binary case. We also show that large-scale monolingual data is still needed to create more accurate models, despite recent advances in multilingual approaches. An error analysis and experiments with multi-label classification show the difficulty of classifying certain types of toxic comments that appear less frequently in our data and highlights the need to develop models that are aware of different categories of toxicity.

1 Introduction
Social media can be a powerful tool that enables virtual human interactions, connecting people and enhancing businesses’ presence. On the other hand, since users feel somehow protected under their virtual identities, social media has also become a platform for hate speech and use of toxic language. Although hate speech is a crime in most countries, identifying cases in social media is not an easy task, given the massive amounts of data posted every day. Therefore, automatic approaches for detecting online hate speech have received significant attention in recent years (Waseem and Hovy, 2016; Davidson et al., 2017; Zampieri et al., 2019b). In this paper, we focus on the analysis and automatic detection of toxic comments. Our definition of toxic is similar to the one used by the Jigsaw competition, where comments containing insults and obscene language are also considered, besides hate speech. Systems capable of automatically identifying toxic comments are useful for platform’s moderators and to select content for specific users (e.g. children). Nevertheless, there are multiple challenges specific to process toxic comments automatically, e.g. (i) toxic language may not be explicit, i.e. may not contain explicit toxic terms; (ii) there is a large spectrum of types of toxicity (e.g. sexism, racism, insult); (iii) toxic comments correspond to a minority of comments, which is fortunate, but means that automatic data-driven approaches need to deal with highly unbalanced data.

Although there is some work on this topic for other languages – e.g. Arabic (Mubarak et al., 2017) and German (Wiegand et al., 2018) –, most of the resources and studies available are for English (Davidson et al., 2017; Wulczyn et al., 2017; Founta et al., 2018; Zampieri et al., 2019b). For Portuguese, only two previous works are available (Fortuna et al., 2019; de Pelle and Moreira, 2017) and their datasets are considerably small, mainly when compared to resources available for English.

We present ToLD-Br (Toxic Language Dataset for Brazilian Portuguese), a new dataset with Twitter posts in the Brazilian Portuguese language.

---

1https://www.kaggle.com/c/jigsaw-toxic-comment-classification-challenge/overview
2This is also similar to the usage of offensive comments in OffensEval (Zampieri et al., 2019b).
3A large list of resources is available at http://hatespeechdata.com
4It is important to distinguish the language variant, since
A total of 21K tweets were manually annotated into seven categories: non-toxic, LGBTQ+phobia, obscene, insult, racism, misogyny and xenophobia. Each tweet has three annotations that were made by volunteers from a university in Brazil. Volunteers were selected taking into account demographic information, aiming to create a dataset as balanced as possible in regarding to demographic group biases. This is then the largest dataset available for toxic data analysis in social media for the Portuguese language and the first dataset with demographic information about annotators.5

We experiment with Brazilian Portuguese (Souza et al., 2019) and Multilingual (Wolf et al., 2019) BERT models (Devlin et al., 2019) for the binary task of automatically classifying toxic comments, since similar models achieve state-of-the-art results for the same task in other languages (Zampieri et al., 2019b). Models fine-tuned on monolingual data achieve up to 76% of macro-$F_1$, improving 3 points over a baseline. Besides, BERT-based approaches with multilingual pre-trained models enable transfer learning and zero-shot learning. The OffensEval 2019 OLID dataset (Zampieri et al., 2019a) is then used to experiment with (i) transfer-learning: where both OLID and ToLD-Br are used to fine-tune BERT; and, (ii) zero-shot learning: where BERT is fine-tuned using only OLID. Results highlight the importance of language-specific datasets, since transfer learning does not improve over monolingual models and zero-shot learning achieves only a macro-$F_1$ of 56%.

An error analysis is performed using our best model, where the worst-case scenario, i.e., classifying toxic comments as non-toxic, is further investigated, taking into account the fine-grained categories. Results show that categories with fewer examples in the dataset (racism and xenophobia) are more likely to be mislabelled than other classes, with the best performance being achieved by majority classes (insult and obscene). We also analyse the amount of data needed in order to achieve the best performance in binary classification. Models trained with few examples are only accurate in predicting the majority class (non-toxic). As the number of instances grows, the performance on the minority class (toxic) improves significantly.

Finally, we experiment with multi-label classification, where each different type of toxicity is automatically classified. This is a considerably harder problem than binary classification, where BERT-based models do not outperform the baseline.

Section 2 presents an overview of relevant previous work. Section 3 shows details about the ToLD-Br dataset. Material and methods are presented in Section 4, whilst results are discussed in Section 5. Finally, Section 6 shows a final discussion and future work.

2 Related Work

Although multiple researchers have addressed the topic of hate speech (e.g. Waseem and Hovy (2016), Chung et al. (2019), Basile et al. (2019)), we focus the literature review on previous work related to toxic comments detection, the topic of our paper. Due to space constraints, we only describe papers that create and use Twitter-based datasets and/or focus on the Brazilian Portuguese language.

English Davidson et al. (2017) present a dataset with around 25K tweets annotated by crowd-workers as containing hate, offensive language, or neither. They build a feature-based classifier with TF-IDF transformation over n-grams, part-of-speech information, sentiment analysis, network information (e.g., number of replies), among other features. Their best model, trained using logistic regression, achieves a macro-$F_1$ of 90. Founta et al. (2018) also rely on crowd-workers to annotate 80K tweets into eight categories: offensive, abusive, hateful speech, aggressive, cyberbullying, spam, and normal. They perform an exploratory approach to identify the categories that cause most confusion to crowd-workers. Their final, large-scale annotation is done using four categories: abusive, hateful, normal, or spam. OffensEval is a series of shared tasks focusing on offensive comments detection (Zampieri et al., 2019b, 2020). The OLID dataset (used in the 2019 edition) has around 1.4K tweets in English manually annotated as offensive or non-offensive. The best model for the relevant task A (offensive versus non-offensive) uses a BERT-based classifier and achieves 82.9 of macro-$F_1$.

German A shared task (organized as part of GermEval 2018) aimed to classify tweets in German categorized into offensive or non-offensive (Wiegand et al., 2018). They make available a manually annotated dataset with approximately 8.5K tweets.
The best system achieved 76.77 of F1-score and was a feature-based ensemble approach.

**Arabic**  Mubarak et al. (2017) present a dataset with 1.1K manually annotated tweets into obscene, offensive, or clean. They experiment with lexical-based approaches that achieve a maximum of 60 F1-score. Mulki et al. (2019) create a dataset with tweets in the Levantine dialect of Arabic manually annotated into normal, abusive, or hate (with approximately 5K tweets). The authors use feature-based approaches to induce models for ternary and binary scenarios, with best systems achieving 74.4 and 89.6 of F1-score, respectively.

**Spanish**  Carmona et al. (2018) present a shared task aiming to detect aggressive tweets in Mexican Spanish. They manually annotate 11K tweets into aggressive or non-aggressive. The best system is a feature-based approach with macro-F1 of 62.

**Hindi**  Mathur et al. (2018) present a dataset of around 3.6K tweets in Hinglish (spoken Hindi written using the Roman script). The dataset was annotated into three classes not offensive, abusive and hate-inducing by ten NLP researchers. A Convolutional Neural Network (CNN) architecture with transfer learning is used, where the model is trained with both Hinglish and English data (from (Davidson et al., 2017)), achieving 71.4% of F1-score.

**Portuguese**  de Pelle and Moreira (2017) make available a dataset with 1,250 comments, extracted from comment sessions of gl1.globo.com website, and annotated them into categories of offensive or non-offensive. The offensive class was also subdivided into racism, sexism, LGBTQ+phobia, xenophobia, religious in-tolerance, or cursing. They experiment with binary classification, using n-grams as features to SVM and NaiveBayes models. Best results are achieved with SVM reaching a weighted F1 score between 77 and 82, depending on different label interpretations. Fortuna et al. (2019) describe a dataset with 5,668 tweets classified as hate vs. non-hate, with the hate class further classified following a fine-grained hierarchy. Experiments with binary classification show a F1 score of 78 using an LSTM-based architecture.

**Multilingual**  HASOC was a shared task aiming to classify hate speech and offensive comments in English, German, and Hindi (Mandl et al., 2019). Their dataset contains around 7K tweets and Facebook posts manually annotated. Sub-task A separates posts into hate speech or offensive versus neither; and, sub-task B separates posts containing hate speech or offence into three categories: hate speech, offensive or profane. Best performing systems in all languages used deep learning approaches. For OffensEval 2020 (Zampieri et al., 2020), a more extensive training data is available for English (over 9M tweets), although the annotation was made semi-automatically. Arabic, Danish, Greek, and Turkish datasets are also available with manually annotated labels. For all languages, best models are achieved using some variation of BERT. Our work is different from previous approaches because we (i) release a large-scale dataset for a language other than English, that was created with the aim to reduce demographic biases; (ii) experiment with multilingual approaches, including transfer learning and zero-shot-learning; (iii) perform an analysis of the amount of data needed to train reliable models; and, (iv) experiment with multilabel classification, providing first insights into this challenge task.

3 Dataset

In this section, we describe the procedure adopted to create ToLD-Br and present its main features.

3.1 Data collection

We used the GATE Cloud’s Twitter Collector⁶ to collect posts on the Twitter platform from July to August 2019. We used two different strategies to select tweets for ToLD-Br, aiming to increase the probability of obtaining posts with toxic content, given that the volume of toxic tweets is significantly smaller than data without offensive language. Our first strategy searches for tweets that mention predefined hashtags or keywords. We chose predefined terms highly likely to belong to a toxic tweet in Brazilian Twitter, such as gay (“Gay tem que apanhar” – “Gay should be beaten up”), mulherzinha (“Mulherzinha, vai lavar louça” – “Sissy, go wash dishes”), and nordestino (“Nordestino preguiçoso” – “Lazy Northeastern”). However, using this strategy alone may hinder learning a model capable of generalising the concept of toxicity beyond the scope of keywords. Consequently, another strategy was adopted: we scraped tweets that mention influential users like Brazil’s president Jair Bolsonaro and soccer player Neymar Jr.

---

⁶https://cloud.gate.ac.uk/shopfront/displayItem/twitter-collector
prone to receive abuse (around 50 influential users were monitored). Tweets collected through this method have no restrictions in terms of keywords and should broaden the scope of the data.

We collected more than 10M unique tweets and randomly selected 21K examples to compose the annotated corpus. We note that 12,600 of these posts (60%) comes from the first strategy – pre-defined keywords – and the remaining are tweets from threads of predefined users. The data was pseudonymised before being sent for annotation, with all @ mentions replaced by @user.

### 3.2 Corpus annotation

The annotation process started by choosing volunteers to perform the task of assigning labels for each example. For this, we made a public consultation at the Federal University of São Carlos (Brazil) to find candidate annotators (129 volunteers registered for the task). From these candidates, 42 were selected based on their demographic information, aiming to balance annotation bias as the interpretation of toxicity may vary. Each annotator labelled 1,500 tweets, selecting one of the following categories: LGBTQ+phobia, obscene, insult, racism, misogyny and/or xenophobia (or leaving it blank for none). Each tweet was annotated by three different annotators.

To evaluate the diversity among the annotators, we explore their profile. We emphasise that the identity of all annotators has been preserved. At this stage, we only survey general aspects of the volunteers who joined the labelling process. Table 1 presents the distribution of annotators regarding sex, sexual orientation, and ethnicity. To define these categories, we use the same values as the Brazilian Institute of Geography and Statistics,\(^7\) in addition to giving the candidate the option of not declaring a value for each characteristic. Although we tried to keep the demographic aspects as balanced as possible when selecting the annotators, our pool of volunteers was still biased towards people identified as white and heterosexual (sex is a more balanced aspect than the others). The age of the annotators varies between 18 and 37 years, with most of them in the range between 19 and 23. Figure 1 illustrates the age distribution.

We perform different data analysis over the dataset to better understand its properties. Inter-annotator agreement is calculated in terms of Krippendorff’s $\alpha$ (Table 2), since $\alpha$ is robust to multiple annotators, different degrees of disagreement and, missing values (Artstein and Poesio, 2008).

The LGBTQ+phobia class shows the highest agreement, which may indicate that comments in this class have a more distinctive lexicon than other classes. The lowest agreement is seen in obscene and racism classes. Besides, we observed in the annotations many cases in which some examples were labelled as separate classes, although they intend

| Categories            | # annotators |
|-----------------------|--------------|
| Sex                   |              |
| Male                  | 18           |
| Female                | 24           |
| Sexual orientation    |              |
| Heterosexual          | 22           |
| Bisexual              | 12           |
| Homosexual            | 5            |
| Pansexual             | 3            |
| Ethnicity             |              |
| White                 | 25           |
| Brown                 | 9            |
| Black                 | 5            |
| Asian                 | 2            |
| Non-Declared          | 1            |

Table 4: The most common words of each class and the number of sentences they occur (within parentheses).

to point the same concept. Classes like obscene and insult seem to have confused the annotators, which may indicate an intersection in these concepts. Table 3 shows examples of disagreements in the classification of obscene and insult.

Table 4 presents the ten most frequent words for each class, after removing stopwords. It confirms the intersection between classes obscene and insult, with six out of ten words in common. For a quantitative analysis, Table 5 presents the Jaccard distance between the 100 most frequent words for each class. Obscene and insult show a considerably lower distance than other pairs (0.57), indicating that they have more words in common.

3.3 Dataset characteristics

For the purpose of training models for automatically classifying toxic comments, we must create aggregated annotations to provide only one binary label for each class. Different rules can be employed to aggregate the annotations, with different semantics. When we set an example as positive for toxicity only when all the annotators consider it to have the same category of offence, we insert bias to the model to not accuse a comment as toxic unless the offence is evident. Since this is very restrictive, we can also use the majority rule, but there must still be a consensus among the annotators. A last option is to consider that only a positive annotation is sufficient to label the example as positive. This procedure acknowledges that annotators may have divergent views about what was said. It is a risky rule if we intend to create rigid systems that classify the tweets and take corrective or prohibitive actions. However, it is beneficial for training a model that “raises a flag” to help moderators to assess the com-

4 Materials and Methods

In this section, we describe the techniques, tools, and other materials used in our experimental evaluation. As mentioned before, we restrict our experiments on the dataset labelled as positive when at least one annotator considers the example as toxic. We then investigate the effects of the number of instances in the training data, different algorithms to train a classification model, various scenarios considering single- and multilingual models, and perform an initial experiment with multi-label classification.

We use Bag-of-Words (BoW) to represent the examples and an AutoML model to build the baseline model (BoW+AutoML). For this, we use the auto-sklearn library (Feurer et al., 2019). For our BERT-based models, we use the simpletransformers library, that allows easy training and evaluation. We use default arguments for parameter tuning and define a seed to allow for reproducibility. Two versions of pre-trained BERT language models are applied: Brazilian Portuguese BERT (Souza et al., 2019), and Multilingual BERT (Wolf et al., 2019).

ToLD-Br is used to fine-tune BERT-based models for our monolingual experiments, with monolingual BERT (BR-BERT) and multilingual BERT (M-BERT-BR). Although M-BERT-BR refers to the multilingual version of BERT, we refer to these two models as “monolingual models,” as we trained using the dataset with Brazilian Portuguese sentences alone.

Using the multilingual model, we also carry out experiments in which we add data in English to train the models either through transfer learning or zero-shot learning. For these experiments we use the OLID data, concatenating the training and test splits into a single dataset. For transfer learning, we merged OLID and ToLD-Br to obtain a model with both languages as input, aiming to assess whether extra data in English helps in building better models (M-BERT(transfer)). For zero-shot learning, OLID is used alone at training time, building a model that did not have access to any data in Brazilian Portuguese (M-BERT(zero-shot)).

---

8 https://automl.github.io/auto-sklearn
9 github.com/ThilinaRajapakse/simpletransformers
10 huggingface.co/neuralmind/bert-base-portuguese-cased
11 huggingface.co/bert-base-multilingual-cased
Through these experiments, we can assess the advantages of monolingual models, whether data from another language can directly benefit the classification, and whether a specific monolingual dataset is necessary or not.

We experiment with different sizes of the training set to assess the influence of the volume of data on the classification. For that, we evaluate the results on random subsets of the data. The size of each partition varies in a range between 10% and 100% adding 10% of the data at each iteration. For each step, we repeat the classification three times to minimise the probability of reporting results obtained by chance. Our best model (M-BERT-BR) is used for this experiment (c.f. Section 5).

Evaluation for binary classification is done in terms of precision, recall and, $F_1$-score per class and macro-$F_1$. We also analyse the confusion matrices of our systems in order to better visualise the performance of our models in each class, mainly focusing on an analysis of false negatives.

Although we mainly focus on binary classification, an initial approach for multi-label classification is also presented. We use the adaptation for the multi-label classification scenario available in simpletransformers. In this case, the transformer’s output consists of six neurons, each representing one of the labels. These neurons are considered independent in the training and prediction process. Thus, when an output neuron is activated, we set the label represented by this neuron to positive. Besides, we evaluate the performance of a baseline based on BoW+AutoML, where we train an AutoML model for multilabel classification. Evaluation is done in terms of Hamming loss and average precision (Tsoumakas et al., 2009).

## 5 Results and Discussion

This section shows the results of our experiments in classifying toxic comments using ToLD-Br.

### 5.1 Binary Classification

For evaluating our models, we are particularly interested in models with high performance in the positive class (classification of toxic comments). The worst case scenario are false negatives, i.e. toxic comments classified as non-toxic. Tables 7 through 11 summarises the results for each model. BoW+AutoML is already a competitive model, achieving 74% of macro-$F_1$, as shown in Table 7 and Figure 2a.

| Precision | Recall | F1-score |
|-----------|--------|----------|
| 0         | 0.76   | 0.75     |
| 1         | 0.71   | 0.73     |
| Macro Avg | 0.74   | 0.74     |
| Weighted Avg | 0.74 | 0.74     |

| Macro Avg | 0.61   | 0.58     |
| Weighted Avg | 0.61 | 0.60     |

Table 10: M-BERT(transfer)

The monolingual models BR-BERT and M-BERT-BR (Tables 8 and 9, respectively) show very similar performances in all metrics, with BR-BERT being slightly better in terms of macro-$F_1$. However, M-BERT-BR is better in terms of $F_1$-score for the positive class and shows fewer false negatives than BR-BERT (Figure 2b for BR-BERT and Figure 2c for M-BERT-BR).

M-BERT(transfer) (Table 10) does not out-
perform the monolingual models and it also shows more false negatives than M-BERT-BR (Figure 2e). On the other hand, the number of false negatives in BR-BERT (267) is slightly higher than the number of false negatives in M-BERT(transfer) (207). Finally, M-BERT(zero-shot) (Table 11) is the worst model, as expected. It performs particularly bad when classifying the positive class, achieving only 43% of $F_1$-score for this class, mainly caused by its high number of false negatives (Figure 2d).

In summary, transfer learning does not seem to improve over the overall performance of monolingual models. Based on the analysis of false negatives, M-BERT-BR appears as our best model. Zero-shot learning shows a very low performance, being particularly bad in the positive class.

**Error Analysis**  We also analyse the performance of our best model (M-BERT-BR) in each fine-grained class. The idea is to identify which toxic classes are most difficult to be classified as toxic by our binary classifier. As false negatives are a critical type of error in our application, Table 12 shows the false negative rate (false negatives / expected positives) for each toxic class. The ratio of false negatives is inversely proportional to the number of examples for a specific class. *Insult* and *obscene*, the largest classes, show the lowest false negative rate, whilst the highest rates are shown by classes with less examples (*racism* and *xenophobia*). Therefore, in order to improve classification models, these aspects of the imbalanced data need to be taken into account and further studied.

| False negative rate |  |
|---------------------|---|
| LGBTQ+phobia        | 7/35 (0.2) |
| Insult              | 67/448 (0.15) |
| Xenophobia          | 13/19 (0.68) |
| Misogyny            | 7/45 (0.15) |
| Obscene             | 117/701 (0.17) |
| Racism              | 8/17 (0.47) |

Table 12: Error analysis for each label.

### 5.2 Importance of Large Datasets

In this experiment, we highlight the importance of collecting a considerable amount of examples, as toxicity can be expressed in many different ways. We separated the training data into 10 random splits from 10% to 100% of the data, increasing 10% of data at each step, and trained M-BERT-BR with three random samples for each step. Figure 3 shows the mean recall, precision and $F_1$-score for the positive and negative classes, respectively, for each
5.3 Multi-Label Classification

We experiment with multi-label classification, building a model using the Multilingual BERT (similar to M-BERT-Br). Our baseline is a set of BoW+AutoML models trained using Binary Relevance (Tsoumakas et al., 2009) for multi-label classification. The BERT-based models adopt a score threshold of 0.5 in the output neuron to deal with multi-label. If the activation for a label in the output layer is higher than the threshold, we consider it positive.

The baseline model obtained 0.08 and 0.20 of Hamming loss and average precision, respectively, while M-BERT-Br resulted in 0.07 and 0.19 for these measures, respectively. Figure 4 displays the confusion matrices obtained by M-BERT-Br.

Figure 4: Confusion matrices for each label (a) LGBTQ+phobia; (b) Obscene; (c) Insult; (d) Racism; (e) Misogyny; (f) Xenophobia.

This scenario is considerably more challenging than binary classification. The positive class of each label corresponds to a subset of the examples labelled as toxic. Thus, it is likely that the number of instances for these classes will be insufficient for the model to learn. Besides, the problem of unbalanced classes becomes evident (c.f. Table 6). As a consequence, it is clear that labels with a small number of positive examples, like racism, misogyny, xenophobia, and LGBTQ+phobia were almost entirely classified as negative. In contrast, for obscene and insult, labels with a considerable amount of positive examples, the model was capable of classifying some examples correctly. In all cases, besides insult, the baseline performs slightly better for the positive class (which justify the higher Hamming loss). This setback is likely due to the difficulty of the neural model to learn with few examples.

6 Concluding Remarks

In this paper, we present ToLD-Br: a dataset for the classification of toxic comments on Twitter in Brazilian Portuguese. Through a wide and comprehensive analysis, we demonstrated the need for this dataset for studies on automatic classification of toxic comments. We highlight that monolingual approaches for this task still outperform multilingual experiments and that large-scale datasets are needed for building reliable models. Also, we show that there are still challenges to be overcome, such as the naturally significant class imbalance when dealing with multi-label classification.

As future work, in addition to deal with class imbalance, we intend to evaluate if aggregating classes with high divergences between annotators can build more reliable models. Besides, we intend to assess the benefits of adding unlabelled data to ToLD-Br to use semi-supervised techniques.

7 Acknowledgements

We thank the volunteers from UFSCar that made this research possible. The MIDAS group12 from the Federal University of São Carlos (UFSCar), Brazil, funded the annotation process. The SoBigData TransNational Access program (EU H2020, grant agreement: 654024) funded Diego Silva and João Leite’s visits to the University of Sheffield.
