Subjecting a many-body localized system to a time-periodic drive generically leads to delocalization and a transition to ergodic behavior if the drive is sufficiently strong or of sufficiently low frequency. Here we show that a specific drive can have an opposite effect, taking a static delocalized system into the many-body localized phase. We demonstrate this effect using a one-dimensional system of interacting hardcore bosons subject to an oscillating linear potential. The system is weakly disordered, and is ergodic absent the driving. The time-periodic linear potential leads to a suppression of the effective static hopping amplitude, increasing the relative strengths of disorder and interactions. Using numerical simulations, we find a transition into the many-body localized phase above a critical driving frequency and in a range of driving amplitudes. Our findings highlight the potential of driving schemes exploiting the coherent destruction of tunneling for engineering long-lived Floquet phases.

A key obstacle in the search for new non-equilibrium quantum phases of matter is the tendency of closed quantum many-body systems to indefinitely absorb energy from a time-periodic driving field. Thus, in the long time limit, such systems generically reach a featureless infinite-temperature-like state with no memory of their initial conditions [1–8]. Interestingly, this infinite temperature fate can be avoided by the addition of disorder [9–13]. Sufficiently strong disorder added to a clean interacting system may lead to a many-body localized (MBL) phase [14–18] which does not allow transport of energy and particles. The MBL phase can persist in the presence of a weak, high-frequency drive [9–13]. Periodically driven systems in the MBL phase retain memory of their initial conditions for arbitrarily long times. Thus, they can support non-equilibrium quantum phases of matter, including some which are unique to the non-equilibrium setting [19–30].

Generically, subjecting an MBL system to a periodic drive increases the localization length [9–11]. If the driving is done at sufficiently low frequencies or high amplitudes, it may even cause the system to exit the MBL phase. This delocalization effect is caused by transitions such as photon-assisted hopping, which are mediated by the periodic drive. These transitions conserve energy only modulo $\hbar \omega$, and can therefore lead to new many-body resonances which destabilize localization.

An oscillating linear potential (henceforth an AC electric field) has a more subtle effect, as it can effectively suppress the hopping amplitude between adjacent lattice sites. This effect, called dynamical localization [33] or coherent destruction of tunneling [34], has been implemented in cold atoms [35–37], and can be used, for example, to induce a transition from a superfluid to a Mott insulator [38, 39]. In non-interacting systems, dynamical localization can be employed to tune the localization properties and relaxation dynamics of one-dimensional disordered lattices [40–44]. In an interacting disordered system, we expect the suppression of the hopping amplitude to increase the relative strengths of disorder and interactions, potentially driving a static delocalized system towards the MBL phase (Fig. 1, inset). However,
it is unclear to what extent the phenomenon of dynamical localization, obtained to lowest order in inverse frequency expansions, still applies in interacting systems, where these expansions often diverge in the thermodynamic limit at any finite driving frequency \[1, 7, 45\].

Here, we demonstrate that an AC electric field affects disordered many-body systems very differently than generic time-periodic drives. In fact, we show that an ergodic (delocalized) system subjected to an AC electric field may transition into the MBL phase. Our results are summarized in Fig. 1, displaying the phase diagram of a one-dimensional many-body system which would be ergodic in the absence of driving. Our main finding is a driving induced MBL phase emerging in a range of driving amplitudes above a critical driving frequency.

**Model.** We consider interacting hardcore bosons hopping on a disordered one-dimensional lattice with periodic boundary conditions at half filling. The particles hop between neighboring sites with a hopping amplitude \(J\); they interact with nearest-neighbor repulsion \(U\), and are subject to random on-site potentials \(V_i\) drawn uniformly and independently from the interval \([-W, W]\).

The static Hamiltonian in the absence of driving therefore takes the form:

\[
H_{\text{stat}}(J, U, W) = J \sum_i \left( \hat{c}_i \hat{c}_{i+1} + h.c. \right) + \sum_i V_i \hat{n}_i + U \sum_i \hat{n}_i \hat{n}_{i+1} \tag{1}
\]

Variants of this model have been studied extensively \([17, 31, 32, 46]\), and feature a transition to a many-body localized phase for sufficiently strong disorder. Specifically, starting from any point in the phase diagram in the space of normalized disorder \(W/J\) and interactions \(U/J\), and decreasing the hopping amplitude \(J\), leads to the MBL phase (Fig. 1).

We investigate the effect of subjecting this static system to an AC electric field. We work in a gauge where the AC electric field is induced by a temporally oscillating, spatially uniform vector potential, rather than by a scalar potential. Using periodic boundary conditions, our system is thus equivalent to a ring penetrated by an oscillating magnetic flux. Parameterizing the electric field as \(E(t) = A \cos(\omega t)\), the Peierls substitution \([47]\) yields a complex phase for the hopping amplitude, replacing \(\hat{c}_i \hat{c}_{i+1}\) in Eq. (1) with \(\hat{c}_i \hat{c}_{i+1} e^{-i(A/\omega) \sin(\omega t)}\).

Intuitively, the AC field can lead to an effective suppression of the hopping amplitude \(J\) due to destructive interference. This effect can be directly seen by considering the time-averaged Hamiltonian:

\[
H_{\text{eff}} = \frac{1}{T} \int_0^T H_{\text{driven}}(t) \, dt = H_{\text{stat}}(J_{\text{eff}}, U, W) \tag{2}
\]

While the disorder and interaction terms remain unchanged, time-averaging the oscillating phase yields a renormalized effective hopping amplitude \(J_{\text{eff}}/J = J_0(A/\omega)\), where \(J_0\) is the zeroth Bessel function. Expanding in Fourier modes we obtain:

\[
H(t) = H_{\text{eff}} + \sum_{n \neq 0} J_n(A/\omega) \hat{c}_{i+1}^\dagger \hat{c}_i e^{-i\omega_n t} + h.c. \tag{3}
\]

where \(J_n\) are the Bessel functions of order \(n\). For fixed \(V, U\), we denote by \(J_c\) the critical hopping amplitude for localization in the undriven model \(H_{\text{stat}}\). When \(|J_{\text{eff}}|\) is larger than \(J_c\), the time-averaged Hamiltonian \(H_{\text{eff}}\) is delocalized \([48]\). Therefore, for \(|J_{\text{eff}}| > J_c\) we expect the driven system to remain in the delocalized phase.

For \(|J_{\text{eff}}| < J_c\), the time-averaged Hamiltonian \(H_{\text{eff}}\) enters the MBL phase. Since the drive consists of a sum of local and bounded operators \(\sum n \neq 0 |J_n|^2 \leq 1\), energy absorption is suppressed at sufficiently high driving frequencies \([49]\). Therefore, we expect the driven system to become localized above a critical driving frequency \([9–11, 50]\).

To predict the shape of the phase diagram (Fig. 1), we note that eigenstates of \(H_{\text{eff}}\) coupled by a local operator can only differ within a range of the order \(\xi\) of the operator’s support \([51–54]\), where \(\xi\) is the localization length. Absorption of energy from the drive is therefore expected to be suppressed if the driving frequency \(\omega\) is larger than the typical local spectrum of a subsystem of size \(\xi\) \([9]\). Consequently, the critical frequency for inducing localization should be minimal when the rescaled driving amplitude \(A/\omega\) is tuned to a root of the Bessel function \((J_{\text{eff}} = 0\)\). In this case, \(H_{\text{eff}}\) is trivially localized with \(\xi = 1\), and commutes with the particle occupations \(n_i\). With increasing \(|J_{\text{eff}}|\), the localization length \(\xi\) becomes larger, and the local spectrum grows accordingly \([55]\). We therefore expect the critical frequency to increase with \(|J_{\text{eff}}|\), until it diverges at \(|J_{\text{eff}}| = J_c\) where \(H_{\text{eff}}\) delocalizes.

**Numerical simulations.** To establish the existence of the driving induced MBL phase, we tune the parameters of our static Hamiltonian to the delocalized phase: \(U = 1.5J, W = 2J\). We then test whether it becomes localized for various driving frequencies and amplitudes near the first root of the zeroth Bessel function, \((A/\omega)^*\). Specifically, we examine the quasiequilibrium level statistics of the evolution operator over one driving period \(U(T) = \mathcal{P} e^{-\frac{i}{T} \int_0^T H(t) \, dt}\) up to a system size \(L = 16\), and the relaxation time in time of an initially prepared product state (up to \(L = 20\)). We first establish localization for strong driving at high frequencies, and then look at the effect of lower frequencies.

**Finite-size scaling of quasiequilibrium level statistics.** We compute \(U(T)\) by exponentiating \(H(t)\) at discrete time-steps (120 equally spaced steps) using exact diagonalization (ED). We then diagonalize \(U(T)\) to obtain the
quasienergies $\epsilon_{\alpha}$, and focus on the gaps between subsequent quasienergies $\delta_{\alpha} = \epsilon_{\alpha+1} - \epsilon_{\alpha}$. The ratio between subsequent gaps averaged over the quasienergy spectrum $\langle r \rangle = \langle \min(\delta_{\alpha}, \delta_{\alpha+1}) \rangle / \langle \max(\delta_{\alpha}, \delta_{\alpha+1}) \rangle$ measures the repulsion between quasienergy levels, and distinguishes between the MBL and ergodic phases of a driven system. The ergodic, delocalized phase exhibits quasienergy level repulsion with a level spacings parameter $\langle r \rangle_{\text{COE}} \approx 0.53$ corresponding to the circular orthogonal ensemble (COE) of random matrices [1]. The MBL phase features uncorrelated Poisson quasienergy level statistics and therefore a smaller value $\langle r \rangle_{\text{POI}} \approx 0.39$ [10, 17, 56].

We begin by considering a fixed frequency $\omega = 5J$ and increasing driving amplitudes (see Fig 2). We observe a sharp change in the scaling of the level statistics with the system size as we increase the driving amplitude. When the system is weakly driven, the level statistics parameter becomes larger as the system size is increased, approaching the delocalized value $\langle r \rangle_{\text{COE}} \approx 0.53$ in a similar manner to the undriven case [31]. However, at sufficiently strong driving the effective hopping $J_{\text{eff}}/J = J_0 (A/\omega)$ is suppressed, and this trend is reversed: the level statistics parameter decreases as the system size is increased, approaching the MBL value $\langle r \rangle_{\text{POI}} \approx 0.39$. Thus, the drive induces a transition from the delocalized phase into the MBL phase. At even stronger driving amplitudes $|J_{\text{eff}}|$ rises again, and the delocalized phase is recovered.

We estimate the critical values of $J_{\text{eff}}$ for the transitions between the MBL and ergodic phases (marked in Fig. 1) at the crossings of the curves for different system sizes $L$ according to finite-size scaling (see Supplemental Materials).

The width (standard deviation) of the many-body spectrum of $H_{\text{stat}}$ in the system sizes we studied with ED is comparable to the driving frequency. This renders resonant absorption of energy from the drive less prominent than in the thermodynamic limit. To confirm the existence of the driving induced localized phase, we study larger systems by propagating an initial density pattern in time.

Relaxation of an initial product state. We initialize our system in an arbitrary product state of site occupations, distributing $L/2$ particles randomly among its $L$ sites. We then evolve this state for a long time by acting on it with the exponential of the Hamiltonian at discrete time steps (120 steps per period for over 1500 driving periods), and follow the site occupations $\langle \hat{n}_i(t) \rangle$. In the absence of driving, the particles spread throughout the system, such that the occupation in each site eventually revolves around $\langle \hat{n}_i \rangle \approx 0.5$ (Fig. 3a, bottom), as expected for an ergodic system [57, 58].

When we evolve the same state with a strong drive at high frequency ($\omega = 5J$), the particles remain mainly in their initial positions for the duration of our simulations (Fig. 3a, top). This indicates long-term memory of the initial conditions, a signature of the MBL phase, as expected from the ED results. Following [13, 58–62], we differentiate between the MBL and delocalized phases by tracking the evolution of the generalized imbalance, which measures the correlation between the current and initial density patterns,

$$I(t) = \frac{4}{L} \sum_{i=1}^{L} |\langle \hat{n}_i(0) - \frac{1}{2} \rangle |\langle \hat{n}_i(t) - \frac{1}{2} \rangle |\psi(0)\rangle.$$

The imbalance generalizes a technique used in recent cold atom experiments, which studied the relaxation of an initially prepared charge-density-wave [60, 61].

In the absence of driving, the system is ergodic, and the density pattern becomes uncorrelated with the initial pattern. Thus, the imbalance decays to a value which decreases with system size (Fig. 3b, c). When a drive of appropriate frequency and amplitude is applied, memory of the initial occupancy pattern persists for long times, and the imbalance stabilizes on a finite value independent of the system size ($I \approx 0.6$ for $\omega = 5J$, $J_{\text{eff}} = 0$). Thus, in the strong driving regime the system fails to thermalize, indicating that an MBL phase is induced by
the driving field.

**Critical driving frequency.** Tuning the rescaled driving amplitude $A/\omega$ to the first root of $J_0$ (such that $J_{\text{eff}} = 0$) and repeating the level statistics analysis for varying frequencies, we find a minimal critical frequency $\omega_c \approx 4J$ for inducing localization with the driving field and model parameters we considered. Below this frequency, the level statistics parameter $\langle r \rangle$ tends to its delocalized value as the system size increases (Fig. 4). Ergodicity at $\omega = 3.5J$ is further confirmed by the analysis of the long-time imbalance of initial product states (Fig. S1 in Supplemental Materials).

As discussed above, we expect the critical frequency for inducing the MBL phase in our system to increase with $|J_{\text{eff}}|$. This expectation is indeed confirmed by the phase diagram in Fig. 1, which we obtained by analyzing the level statistics for additional cuts of fixed frequency in parameter space (see Fig. S2 for data near $\omega_c$). Finally, we find qualitatively similar results with a slightly reduced critical frequency when the driving amplitude is tuned near the second root of $J_0$; when the system is taken at a smaller filling fraction; or when a square-wave drive is used (for details, see Supplemental Materials).

**Discussion.** We have shown that subjecting an ergodic system to a periodic drive can induce a transition into the MBL phase, providing an interesting example for the emergence of integrability in an ergodic system due to the addition of a drive. It would be interesting to understand how the phase diagram (Fig. 1) depends on the strength of disorder and interactions, and specifically,
whether MBL can be induced in our model starting from arbitrarily weak disorder. Especially interesting are possible generalizations to higher dimensions, for example by using circularly polarized electromagnetic fields in two dimensions [63]. Most importantly, our results open new possibilities for inducing exotic out-of-equilibrium phases in weakly disordered systems using methods which are readily accessible in cold atom systems [35, 37, 61].

Note added: During the completion of this manuscript, we became aware of recent works which find localization enhancement in the driven quantum random energy model [64], and a driving induced MBL phase in spin chains [65].

SUPPLEMENTAL MATERIALS: DRIVING INDUCED MANY-BODY LOCALIZATION

A. Relaxation of initial product states at low frequencies

In addition to the increase of the level statistics parameter with system size, the lack of localization at low driving frequencies is also manifested in the relaxation of initial product states of particle occupations. When these states are driven at $\omega = 3.5J$, their generalized imbalance decays to a value which decreases with system size (Fig. S1), as in the undriven case. Note that the decay as a function of time is slower when compared to the decay in the undriven case. Presumably, this is due to the proximity to the MBL transition [62] for this value of the driving frequency.

As the driving frequency approaches the speculated critical frequency $\omega_c \approx 4J$, the remaining imbalance at long times declines much slower with system size (Fig. S1 inset). The quick flattening of the slope in the inset of Fig S1, for a small change of driving frequency, provides an independent corroboration for the value of the critical frequency.

B. Phase boundaries between the ergodic and MBL phases

The phase boundaries in Fig. 1 were obtained by finite-size scaling of the quasienergy level statistics $\langle r \rangle$. Examples of such data are given in Figs. 2, 4, S2. Namely, a consistent increase of $\langle r \rangle$ with system size is interpreted as an indication for the ergodic phase, while a consistent decrease of $\langle r \rangle$ with system size is interpreted as an indication for the MBL phase. Error bars indicate parameter ranges where the trend in level statistics with increasing system size is not statistically significant (according to the error bar for $\langle r \rangle$, as shown for example in Figs. 2, 4, S2).

At $\omega = 5J$ we found driving induced many-body localization in a range of driving amplitudes around $(A/\omega)^*$, corresponding to the first root of $J_0$, for which $J_{\text{eff}} = 0$. At $\omega = 4J$, the level statistics parameter at $(A/\omega)^*$ changes very slowly with system size, indicating proximity to the critical frequency; at a lower frequency $\omega = 3.5J$, the level statistics parameter tends to the delocalized value at any driving amplitude $A/\omega > 0$ up to the first minimum of $J_0$.

C. Level statistics as a function of driving amplitude at low frequencies

At $\omega = 5J$ we found driving induced many-body localization in a range of driving amplitudes around $(A/\omega)^*$, corresponding to the first root of $J_0$, and for which $J_{\text{eff}} = 0$ (Fig. 2 in main text). We expect this range to narrow for lower driving frequencies, and to vanish altogether for $\omega < \omega_c \approx 4J$; at these frequencies, the drive fails to induce localization even at $J_{\text{eff}} = 0$ (Fig. 4). Indeed, when we perform finite-size scaling of the level statistics as a function of driving amplitude at frequencies lower than $5J$, we find that the range of localization-inducing driving amplitudes continuously narrows, and all but shrinks to a point $J_{\text{eff}} = 0$ at $\omega = 4J$ (Fig. S2 left, middle). Below this frequency, the level statistics parameter increases with system size for any driving amplitude $A/\omega > 0$ up to the first minimum of $J_0$ (Fig. S2 right, right).
right), indicating that the drive fails to induce localization for this range of driving amplitudes.

D. Driving induced MBL beyond the first minimum of $J_0$

So far, we have analyzed a range of driving amplitudes $0 \leq A/\omega \leq (A/\omega)_{\text{min}}$, where $(A/\omega)_{\text{min}}$ is the first minimum of the Bessel function (bright green in Fig. S3b). We performed additional simulations which suggest a qualitatively similar phase diagram at higher driving amplitudes.

Specifically, we obtained the finite-size scaling of the quasienergy level statistics for driving amplitudes corresponding to the interval between the first minimum of $J_0$ to its next maximum (dark green in Fig. S3b). The result of this analysis also shows localization in a range of driving amplitudes above a critical driving frequency.

To determine the critical driving frequency for values of $A/\omega$ corresponding to $(A/\omega)^{**}$, the second root of $J_0$, we varied the driving frequency while tuning the driving amplitude such that $A/\omega$ remains fixed. The results, shown in Fig S3a, indicate that the critical driving frequency for inducing MBL at $(A/\omega)^{**}$ is $\omega_c \approx 3.25J$, which is lower compared to the one found at the first root ($\omega_c \approx 4J$).

This decrease in the critical driving frequency can be understood by comparing the Fourier spectrum of the Hamiltonian at the first two roots of the zeroth Bessel function (Fig. S3c). While the first Fourier mode of the Hamiltonian is the most dominant when $A/\omega$ is tuned to the first root of $J_0$, at the second root of $J_0$ the bulk of its Fourier spectrum shifts to the higher harmonics. Intuitively, driving at a larger amplitude therefore has a similar effect to increasing the driving frequency.

E. Inducing MBL with a square-wave electric field

Our analysis so far focused on an AC electric field oscillating in time as $E(t) = A \cos(\omega t)$. However, the effective hopping in $H_{eff}$ is suppressed also for other functional forms for periodic time dependence of the AC electric field. We tested the possibility to induce an MBL phase with a square-wave AC electric field:

$$E(t) = \begin{cases} 
    A & 0 \leq t < T/2 \\
    -A & T/2 \leq t < T 
\end{cases}$$

(S1)

Such a field can be used for exact dynamical localization in models with hopping beyond nearest-neighbor [36, 66]. In our model, performing the Peierls substitution and time-averaging the acquired phase leads to the effective hopping amplitude:

$$J_{eff}/J = e^{-i \pi \frac{T}{2}} \cdot \text{sinc} \left( \frac{\pi A}{2\omega} \right)$$

(S2)

Again, finite-size scaling of quasienergy level statistics shows localization in a range of driving amplitudes around $J_{eff} = 0$ (here obtained at $A/\omega = 2$) below a critical driving frequency $\omega \approx 3.5J$ (Fig. S4).

Figure S3. Driving induced MBL at a driving amplitude corresponding to $(A/\omega)^{**}$, the second root of $J_0 (A/\omega)$. (a) Finite-size scaling of quasienergy level statistics as a function of driving frequency. The critical frequency at the second root ($\omega_c \approx 3.25J$) is smaller than the one found at the first root, $\omega_c \approx 4J$. (b) Plot of the zeroth Bessel function $J_0$: bright green indicates the amplitude range considered in the main text, additional simulations performed at the dark green amplitude range show qualitatively similar results. (c) Values of the various Bessel functions $J_n$ at the first root $(A/\omega)^{**}$ vs. second root $(A/\omega)^{*}$ (light green) vs. second root $(A/\omega)^{*}$ (dark green) of $J_0 (A/\omega)$, indicating the values of the non-zero Fourier modes of the Hamiltonian when the time-averaged Hamiltonian has no hopping term, $J_{eff} = 0$. The values of the negative orders are related by $J_{-n} (A/\omega) = (-1)^n J_n (A/\omega)$.

Figure S4. Finite-size scaling of quasienergy level statistics $(\tau)$ for the square-wave electric field (S1). Left: as a function of rescaled driving amplitude $A/\omega$ at a fixed driving frequency $\omega = 5J$. Right: as a function of driving frequency for $A = 2\omega$, corresponding to $J_{eff} = 0$ for the square-wave drive [see Eq. (S2)].
F. Driving induced MBL at a lower filling fraction

Our numerical simulations so far focused on the case of half filling. This filling fraction was chosen to maximize the width of the many-body spectrum for a given number of sites, thus minimizing finite-size effects.

We expect qualitatively similar results at different particle fillings. The critical frequency might slightly decrease though, since the interactions become effectively weaker away from half filling (this is apparent when the filling is decreased below 1/2, but is also true when it is increased due to particle-hole symmetry). In the parameter range we use for our simulations, weaker interactions imply stronger localization with a shorter localization length; therefore, the local spectrum becomes narrower and the critical frequency should correspondingly decrease.

To test this, we repeat the procedure of figure 4 at a different filling fraction 1/3 (Fig. S5). Namely, we fix the rescaled driving amplitude $A/\omega$ at the first root of the zeroth Bessel function ($J_{\text{eff}} = 0$) and perform finite-size scaling of the quasienergy level statistics as a function of the driving frequency $\omega$. Indeed, we find that the MBL phase is induced above a critical frequency $\omega \approx 3.75$, which is slightly smaller than the critical frequency $\omega \approx 4$ found at half filling.

![Figure S5. Finite-size scaling of quasienergy level statistics $\langle r \rangle$ at filling fraction 1/3. We tune the driving frequency $\omega$ while fixing the rescaled driving amplitude $A/\omega$ at the first root of the zeroth Bessel function ($J_{\text{eff}} = 0$). We find a critical frequency $\omega \approx 3.75$ for inducing the MBL phase, which is slightly lower than the critical frequency found at half filling ($\omega \approx 4$).](image-url)
