KEYWORDS
Acute respiratory distress syndrome; Mechanical ventilation; Tidal volume; Ventilator-induced lung injury

Abstract
Objective: Evidence only proves low surpasses high tidal volume (VT) for acute respiratory distress syndrome (ARDS). Intermediate VT is a common setting for ARDS patients and has been demonstrated as effective as low VT in non-ARDS patients. The effectiveness of intermediate VT in ARDS has not been studied and is the objective of this study.
Design: A retrospective cohort study.
Setting: Five ICUs with their totally 130 beds in Taiwan.
Patients or participants: ARDS patients under invasive ventilation.
Interventions: No.
Main variables of interest: 28-D mortality.
Result: Totally 382 patients, with 6958 ventilator settings eligible for lung protection, were classified into low (mean VT = 6.7 ml/kg), intermediate (mean VT = 8.9 ml/kg) and high (mean VT = 11.2 ml/kg) VT groups. With similar baseline ARDS and ICU severities, intermediate and low VT groups did not differ in 28-D mortality (47% vs. 63%, P = 0.06) or other outcomes such as 90-D mortality, ventilator-free days, ventilator-dependence rate. Multivariate analysis revealed high VT was independently associated with 28-D and 90-D mortality, but intermediate VT was not significantly associated with 28-D mortality (HR 1.34, CI 0.92–1.97, P = 0.13) or 90-D mortality. When the intermediate and low VT groups were matched in propensity scores (n = 66 for each group), their outcomes were also not significantly different.

**Conclusion:** Intermediate \( V_T \), with its outcomes similar to small \( V_T \), is an acceptable option for ventilated ARDS patients. This conclusion needs verification through clinical trials. © 2022 Elsevier España, S.L.U. y SEMICYUC. All rights reserved.

**PALABRAS CLAVE**
Síndrome de dificultad respiratoria aguda; Ventilación mecánica; Volumen corriente; Lesión pulmonar inducida por ventilación

**El volumen tidal intermedio es una opción aceptable para pacientes ventilados con síndrome de dificultad respiratoria aguda**

**Resumen**
Objetivo: La evidencia solo demuestra que el volumen tidal (\( V_T \)) bajo supera al alto para el síndrome de dificultad respiratoria aguda (ARDS). La \( V_T \) intermedia es un escenario común para los pacientes con ARDS y se ha demostrado que es tan eficaz como la \( V_T \) baja en pacientes sin ARDS. No se ha estudiado la eficacia de la \( V_T \) intermedia en el ARDS y es el objetivo de este estudio.

Diseño: Un estudio de cohorte retrospectivo.

Ámbito: Cinco UCI con un total de 130 camas en Taiwán.

**Resultados**
Un total de 382 pacientes, con 6958 configuraciones de ventilador elegibles para protección pulmonar, se clasificaron en bajo (\( V_T \) medio = 6,7 ml/kg), intermedio (\( V_T \) medio = 8,9 ml/kg) y alto (\( V_T \) medio = 11,2 ml/kg). Grupos de \( V_T \). Con un ARDS inicial similar y una gravedad en la UCI, los grupos de \( V_T \) intermedia y baja no difirieron en la mortalidad 28-D (47% vs. 63%, \( p=0,06 \)) u otros resultados como mortalidad 90-D, días sin ventilador, dependencia del ventilador índice. El análisis multivariado reveló que la \( V_T \) alta se asoció de forma independiente con la mortalidad 28-D y 90-D, pero la \( V_T \) intermedia no se asoció significativamente con la mortalidad 28-D (HR 1,34, IC 0,92-1,97, \( p=0,13 \)) o la mortalidad 90-D. Cuando los grupos de \( V_T \) intermedia y baja se emparejaron en puntajes de propensión (n = 66 para cada grupo), sus resultados tampoco fueron significativamente diferentes.

**Conclusion:** La \( V_T \) intermedia, con resultados similares a la \( V_T \) pequeña, es una opción aceptable para pacientes con ARDS ventilados. Esta conclusión necesita verificación a través de ensayos clínicos. © 2022 Elsevier España, S.L.U. y SEMICYUC. Todos los derechos reservados.

**Introduction**

Mechanical ventilator support remains the cornerstone of acute respiratory distress syndrome (ARDS) management. Many harmful effects of mechanical ventilation, such as ventilator-induced lung injury (VILI), have been recognized and led to the development of a lung-protective ventilatory strategy, mainly by keeping tidal volume (\( V_T \)) low. A well-known study by the ARDS Network in 2000 demonstrated that low \( V_T \) (6 ml/kg predicted body weight, PBW) is better than high \( V_T \) (12 ml/kg PBW) in terms of mortality and ventilator-free days. The superiority of low \( V_T \) in this study may stem more from avoiding the harmful effects of high \( V_T \) (12 ml/kg PBW) and plateau pressure (up to 50 cmH\(_2\)O) than strict adherence to low \( V_T \) per se. This speculation was supported by 3 futile clinical trials in low \( V_T \) before the year 2000. With \( V_T \) around 10 ml/kg PBW and plateau pressure less than 31 cmH\(_2\)O in the control groups, the beneficial effects of low \( V_T \) were completely abolished in these 3 studies. Therefore, we hypothesize that intermediate \( V_T \) (7.5-10 ml/kg PBW), by shunning the deleterious effects of high \( V_T \), could also be lung-protective as low \( V_T \).

Two decades after the publication of the landmark study, low \( V_T \) adherence remains poor throughout the world. A survey of Chicago physicians found that more than 92% knew that patients with ARDS warranted low \( V_T \) ventilation, but they ordered low \( V_T \) in only 7% (0-14%) of their eligible patients. The reasons for nonadherence to low \( V_T \) ventilation are complex. Some physicians are skeptical about applying evidence derived from randomized control trials to critical care practice, some may concern complications of low \( V_T \) such as hypercapnia, air hunger sensation and possible self-inflicted lung injury if there is no adequate sedation or paralysis. Therefore, many physicians adopt a less strict version of lung protection ventilation. Intermediate \( V_T \) was found in some studies to be the most commonly applied ventilator setting for patients with ARDS. Intermediate \( V_T \) has been shown to be as effective as low \( V_T \) for ventilated patients without ARDS in terms of mortality and other clinical outcomes. However, the role of intermediate \( V_T \) in patients with ARDS has not been
carefully studied. Data inferred from a study of 111 real-world patients with ARDS suggest that the mean V̇e of 9.5 ml/kg PBW is not inferior to 6.1 ml/kg PBW in terms of 28-day or 1-year mortality rate. In this study, we retrospectively compared the clinical outcomes of patients with ARDS who received intermediate and low V̇e.

Method

Patient enrollment

We retrospectively collected invasively ventilated patients with ARDS admitted to Changhua Christian Hospital, a medical center with a total of 130 ICU beds in 5 separate wards, between January 2012 and November 2018. These patients were identified by their discharge diagnoses of ARDS and acute respiratory failure in electronic archives. Each diagnosis of ARDS was defined by the Berlin definition and was reconfirmed by one of our pulmonologists (SHW or YCH). Exclusion criteria include age less than 20 or over 90 years, actual body weight less than 40 or over 100 kg, being transferred to other hospital or discharged against medical advice without traceable clinical outcome, a total duration of invasive ventilation less than 48 h, using airway pressure release ventilation or high-frequency oscillation ventilation or extracorporeal membrane oxygenation during the ARDS period, been withdrawn from the ventilator due to hospice, co-morbidities of metastatic malignancy, end-stage heart failure (left ventricular ejection fraction less than 35%) or ventilator-dependence (Invasive ventilation lasting over 21 days before the onset of ARDS), been enrolled in other ARDS-related clinical trials. The patients were followed until death or the 28th day after ARDS was diagnosed. The study was approved by the institutional review board of Changhua Christian Hospital (Approval No. 181214). The Board has waived the requirement for informed consent from participants.

Characteristics of the patients and treatment variables

Baseline variables when ARDS was diagnosed for the first time were collected. They include age, sex, body mass index, acute physiology and chronic health evaluation II (APACHE II) score, sequential organ failure assessment (SOFA) score, co-morbidity, predisposing factors for ARDS and type of ICU admitted. Whether patients received sedation, muscle relaxant, systemic steroid, vasopressor, hemodialysis, continuous hemofiltration, prone position, or total parenteral nutrition during the ARDS period were recorded.

Ventilator setting and monitoring parameters when eligible for lung protection

Ventilator settings were recorded every 8 h until ventilator discontinuation or the 28th day after diagnosing ARDS. If a fraction of inspired oxygen (FIO2) ≥ 50% and positive end-expiratory pressure (PEEP) was greater than 5 cmH2O, it was considered eligible for lung protection. This definition of eligibility was made because it approximated the threshold for a trial of spontaneous breathing without further restriction in V̇e or plateau pressure in the ARDS Network ventilation protocol. V̇e and other ventilator parameters were counted and analyzed only when the occasions were eligible for lung protection. The mean V̇e was categorized based on each patient’s predicted body weight into low (<7.5 ml/kg PBW), intermediate (7.5–10 ml/kg PBW), high (>10 ml/kg PBW). Other parameters collected include airway pressure (peak, mean, plateau, driving), PEEP, respiratory system compliance (Crs), and arterial oxygenation (P5O2, S5O2, P5O2/FIO2 ratio). When patients were under pressure-targeted ventilation and their plateau pressures were not measured directly, we used the peak airway pressure or the sum of PEEP and set increment of inspiratory pressure to represent plateau pressure.

Outcome assessment

The primary outcome was mortality rate of 28 days. Secondary outcome included a 90-day mortality rate, ventilator-free days during the initial 28 days, and ventilator-dependence rate on day 28 (excluding the patient who died within 28 days).

Statistical analysis

Data were expressed as a number (percent), mean ± standard deviation or median, interquartile range (IQR). Each variable was tested for normal distribution using the Kolmogorov-Smirnov test. For the comparison of three groups of continuous variables, we used the analysis of variance or the Kruskal-Wallis analysis of variance test. Regarding categorical variables, the Chi-square or Fisher’s exact test was used when appropriate. The Bonferroni-adjusted post hoc significance test was used to compare low and intermediate V̇e. Uni- and multi-variate Cox proportional hazards regression with backward selection procedure were used to assess hazard ratios (HR) and 95% confidence interval (CI) of mortality. V̇e category was retained in the models as a priori basis. Variables with a P-value of less than 0.10 in the crude model entered the multivariate model during backward selection. The propensity score was calculated by non-parsimonious multi-variable logistic regression. All variables, except respiratory parameters, were considered. Propensity score matching was performed to balance the distributions of measured covariates in the low- and intermediate-V̇e groups. We matched each patient in the low V̇e group with one of the intermediate V̇e group based on propensity scores with a caliper of 0.1 standard deviation unit. All respiratory parameters were tested for collinearities using the variance inflation factor (VIF). A VIF over 2 indicates the presence of collinearity and it was excluded from the model. A P-value of less than 0.05 was considered significant. All statistical analyses were performed using the SPSS statistical package (IBM SPSS Statistics, version 20, IBM Corporation, Chicago, IL, USA).
Result

Totally 786 patients were invasively ventilated for their ARDS and acute respiratory failure. Four hundred and four patients were excluded because of 20 with extreme body weights, 19 without traceable clinical outcomes, 175 invasively ventilated for less than 48 h, 2 ventilated by special modes, 70 received extracorporeal membrane oxygenation during the ARDS period, 4 withdrawn from a life-sustaining machine for hospice, 102 with pre-existing terminal illnesses, 12 without ventilator settings eligible for lung-protective ventilation. Therefore, 382 patients, with a total of 6958 ventilator settings eligible for lung-protective ventilation, were analyzed. A flowchart of patients included in the final analysis was presented in Fig. 1.

The patients were classified into low (mean $V_T = 6.7 \text{ ml/kg PBW}, n = 76, 19.9\%$), intermediate (mean $V_T = 8.9 \text{ ml/kg PBW}, n = 204, 53.4\%$) and high (mean $V_T = 11.2 \text{ ml/kg PBW}, n = 102, 26.7\%$) $V_T$ groups according to their mean $V_T$ while eligible for lung protection. Their baseline characteristics, treatment, and ventilator setting variables are summarized in Table 1. Intermediate and low $V_T$ groups did not differ in their baseline APACHE II or SOFA scores. Both groups also have a comparable baseline ARDS severity distribution. The driving pressures the patients received were not significantly different.

| Systemic steroid, No. (%) | 69 (91) | 172 (84) | 81 (79) | 0.12 | 0.49 |
| Prone position, No. (%) | 15 (20) | 25 (12) | 2 (2) | <0.01 | 0.34 |
| Hemodialysis, No. (%) | 13 (17) | 27 (13) | 10 (10) | 0.36 | 1.00 |
| Continuous hemofiltration, No. (%) | 35 (46) | 72 (35) | 20 (20) | <0.01 | 0.30 |
The outcomes of the three groups are shown in Table 2. Intermediate Vf has similar 28-day mortality with the low Vf group (47.1% vs. 63.2%, P = 0.06). Intermediate and low Vf groups did not differ significantly in other outcomes, such as 90-day mortality, ventilator-free days, ventilator-dependence rate, or barotrauma rate. By Cox regression model analysis, high Vf (HR 1.78, 95% CI 1.08–2.94, P = 0.03), male, low Crs, liver cirrhosis, and high PEEP were independently associated with mortality at 28 days (Table 3). Intermediate Vf was not independently associated with mortality at 90 days. The collinearities of FIO2, PaO2, and Crs were excluded due to their lower than 2 VIF values (Table s2).

Intermediate and low Vf cohorts matched with the propensity score were developed. Their characteristics and outcomes are presented in Table 4. Both groups did not differ in mortality (Fig. 2) and all other clinical outcomes. Multivariate analysis revealed that low Crs and high F1O2 were independently associated with mortality rate of 28- or 90-days, while intermediate Vf was not (Table s3).

**Discussion**

According to several surveys,14,17 intermediate Vf was commonly used in patients with or without ARDS throughout the
Table 3  Factors associated with 28-day mortality.

world. However, our study is the first report on the clinical outcomes of the use of intermediate \( V\textsubscript{T} \) in patients with ARDS.

Some animal studies have confirmed that high \( V\textsubscript{T} \) contributes to VILI.\textsuperscript{26,27} A recent study found that patients ventilated with \( V\textsubscript{T} \) of 12 ml/kg PBW for as short as 4 days could induce lung inflammation.\textsuperscript{28} The well-known study by the ARDS Network showed that high \( V\textsubscript{T} \) has a worse outcome than low \( V\textsubscript{T} \).\textsuperscript{1} Our results also confirm that high \( V\textsubscript{T} \) is independently associated with mortality at 28 and 90 days in patients with ARDS. However, strict adherence to low \( V\textsubscript{T} \) may not be necessary. According to data from our study, intermediate \( V\textsubscript{T} \), by shunning the deleterious effect of high \( V\textsubscript{T} \), has comparable clinical outcomes with low \( V\textsubscript{T} \).

Low \( V\textsubscript{T} \) is not by itself the only factor in preventing VILI. Amato et al. found that \( V\textsubscript{T} \) divided by \( C\textsubscript{RS} \), or driving pressure, is most strongly associated with survival in ARDS.\textsuperscript{29} Gattinoni et al. coined the term 'baby lung' to describe a fraction of the lung parenchyma that maintains normal inflation in patients with ARDS. They argued that \( V\textsubscript{T} \) should be adjusted according to the size of the baby lung and the strain it received during mechanical inflation instead of ideal body weight.\textsuperscript{30} They incorporated \( V\textsubscript{T} \) and a bundle of respiratory parameters to measure the mechanical power lung received during ventilation,\textsuperscript{31} which is considered more accurate in predicting the likelihood of VILI.\textsuperscript{32} Since \( V\textsubscript{T} \) per se is not of utmost importance in preventing VILI, more strict control of \( V\textsubscript{T} \) (i.e., ultralow \( V\textsubscript{T} \)) failed to produce additional benefit as some researchers expected.\textsuperscript{33} Strictly low \( V\textsubscript{T} \) may not be necessary for all patients with ARDS. Several ARDS phenotypes have been identified. About 55% of patients who met the Berlin definition of ARDS do not have typical pathological diffuse alveolar damage. These patients tend to have milder symptoms and shorter clinical courses.\textsuperscript{34} About 10–17% of patients with ARDS were extubated or no longer met the criteria for ARDS in less than 24h.\textsuperscript{35} These subsets of ARDS with their distinct clinical course may warrant personalized treatment. A recently published French trial tested personalized treatment by giving patients with ARDS with focal involvement a \( V\textsubscript{T} \) of 8 ml/kg PBW and those without focal involvement a \( V\textsubscript{T} \) of 6 ml/kg PBW in addition to a bundle of other related ventilatory maneuvers. The per protocol analysis showed that patients in the personalized treatment group have a survival advantage over the control group, who universally received a \( V\textsubscript{T} \) of 6 ml/kg PBW.\textsuperscript{36}

To classify \( V\textsubscript{T} \) as low or not, some observational studies on ARDS only counted the \( V\textsubscript{T} \) patients received in the initial few days.\textsuperscript{6,19} However, this way of counting inappropriately neglected the influences of \( V\textsubscript{T} \) patients received in subsequent days. We adopted the method of Needham et al. by counting all \( V\textsubscript{T} \) patients received for up to 28 days if their ventilator settings were considered eligible for lung protection.\textsuperscript{23} We recorded \( V\textsubscript{T} \) three times per day, more frequently than Needham (twice per day). Based on the mean of all \( V\textsubscript{T} \) patients received throughout the whole ventilation courses, we believe our categorization of \( V\textsubscript{T} \) is more accurate than many previous observational studies on ARDS.
Table 4  Characteristics and outcomes of propensity score-matched cohorts.

|                      | Low $V_T$ (n = 66) | Intermediate $V_T$ (n = 66) | P-value |
|----------------------|--------------------|-----------------------------|---------|

Outcomes

|                      | Low $V_T$ | Intermediate $V_T$ | P-value |
|----------------------|----------|-------------------|---------|
| Ventilator-free days, day 1–28<sup>a</sup>, median (IQR) | 12 (2–18) | 15 (3–19) | 0.51    |
| Ventilator dependence by day 28<sup>a</sup> (%) | 7 (32)    | 8 (25)            | 0.58    |
| 28-Day mortality (%) | 44 (67)   | 34 (52)           | 0.08    |
| 90-Day mortality (%) | 47 (71)   | 37 (56)           | 0.07    |
| Barotrauma (%)       | 6 (9)     | 5 (8)             | 0.75    |

<sup>a</sup> In patients surviving by day 28.

<sup>b</sup> Crs: respiratory-system compliance.

Figure 2  Kaplan–Meier survival curves by day 28 (A) and day 90 (B) for propensity score-matched patients of intermediate and low $V_T$ groups.

The $V_T$ received by our patients were not randomly assigned, but were given according to the in-charge doctors’ choice. We find those receiving low $V_T$ have lower Crs (Table 1), which made higher $V_T$ inappropriate because the limitation of plateau pressure could easily be exceeded. Whereas those with higher Crs were more likely to receive intermediate, rather than low $V_T$. This practice was in line with the global tendency toward nonadherence to low $V_T$<sup>4–8</sup> as we have mentioned in our introduction.

Prone positioning has been proved effective for moderate to severe ARDS patients,<sup>37</sup> but only 12% and 20% (from intermediate and low $V_T$ group respectively, both with a median of $P_{a}O_{2}/F_{I}O_{2} < 150$mmHg) of our patients received this adjunctive therapy. This was just another example of discrepancy between clinical trial and clinical practice. This trend was also universal. The LUNG SAFE study, involving 50 countries around the world, found prone was used in only 6% and 16% of the moderate and severe ARDS patients...
respectively. A recent survey of moderate-to-severe ARDS patients in the US found only 6% of them received prone in their early management. Efforts are needed to find reasons behind the widespread nonadherence.

Liver cirrhosis was found to be an independent risk factor for 28- and 90-day mortality in our patients with ARDS. This finding was in accordance with previous studies. Increased pro-inflammatory interleukin-6 and interleukin-8 in patients with decompensated cirrhosis were thought to contribute to lung injury in those at risk.

There are several limitations to this study. First, it was a retrospective observation. The classification of $V_t$ groups was not assigned randomly. Selection bias and unrecognized confounders are possible. Second, our data were all from one center. The generalizability of our conclusion can be limited. Third, for patients with pressure-targeted ventilation, plateau pressures were not measured directly. We used the peak airway pressure or the sum of PEEP and set increment of inspiratory pressure instead. The plateau pressure derived by this way is prone to overestimation. Driving pressure and $C_{RS}$ calculated from this putative plateau pressure were all subject to imprecision.

In conclusion, we found that high $V_t$ is harmful to patients with ARDS. Intermediate and low $V_t$ and have similar clinical outcomes. Our results suggested that intermediate $V_t$ is an acceptable option for ventilated patients with ARDS. This conclusion needs to be verified by randomized control trials.

Funding

The study was supported by grant number 108-CCH-IRP-012 (Changhua Christian Hospital).

Authors’ contributions

SHW drafted the manuscript. CTK analyzed the data and performed statistical calculations. CYL collected clinical data from study patients. YCH gave final approval of the version to be published.

Conflict of interest

No conflict of interest to declare.

Acknowledgment

We thank Hui-Ching Chen, Kuan-I Lee and Wan-ping Wen for secretarial assistance.

We thank Dr. Lon-Yen Tsao for the critical review of our manuscript.

Appendix A. Supplementary data

Supplementary data associated with this article can be found, in the online version, at doi:10.1016/j.medint.2022.03.016.
