Key Residues and Phosphate Release Routes in the *Saccharomyces cerevisiae* Pho84 Transceptor

THE ROLE OF TYR\(^{179}\) IN FUNCTIONAL REGULATION*\(^{8}\)

Received for publication, May 13, 2016, and in revised form, October 28, 2016 Published, JBC Papers in Press, November 8, 2016, DOI 10.1074/jbc.M116.738112

Edited by Henrik Dohlman

Pho84, a major facilitator superfamily (MFS) protein, is the main high-affinity P\(_i\) transceptor in *Saccharomyces cerevisiae*. Although transport mechanisms have been suggested for other MFS members, the key residues and molecular events driving transport by P\(_i\):H\(^+\) symporters are unclear. The current Pho84 transport model is based on the inward-facing occluded crystal structure of the Pho84 homologue PiPT in the fungus *Piriformospora indica*. However, this model is limited by the lack of experimental data on the regulatory residues for each stage of the transport cycle. In this study, an open, inward-facing conformation of Pho84 was used to study the release of P\(_i\). A comparison of this conformation with the model for P\(_i\) release in PiPT revealed that Tyr\(^{179}\) in Pho84 (Tyr\(^{150}\) in PiPT) is not part of the P\(_i\) binding site. This difference may be due to a lack of detailed information on the P\(_i\) release step in PiPT. Molecular dynamics simulations of Pho84 in which a residue adjacent to Tyr\(^{179}\), Asp\(^{178}\), is protonated revealed a conformational change in Pho84 from an open, inward-facing state to an occluded state. Tyr\(^{179}\) then became part of the binding site as was observed in the PiPT crystal structure. The importance of Tyr\(^{179}\) in regulating P\(_i\) release was supported by site-directed mutagenesis and transport assays. Using trehalase activity measurements, we demonstrated that the release of P\(_i\) is a critical step for transceptor signaling. Our results add to previous studies on PiPT, creating a more complete picture of the proton-coupled P\(_i\) transport cycle of a transceptor.

The major facilitator superfamily (MFS)\(^{4}\) is one of the largest families of secondary active transporters (1). Currently, 64 crystal structures from 10 different families are available, and several of these structures were resolved in substrate-free and substrate-bound conformational states, therefore providing significant insights into the molecular mechanisms involved in nutrient transport (2). The key feature of MFS transporters is that transport across the membrane occurs via an alternating-access mechanism, the “rocker-switch” model (3), which involves a variety of distinct conformations including outward-open, substrate-bound occluded, and inward-open states. A limitation of the rocker-switch model, however, is that because it is based solely on rigid body rotation, it does not explain the presence of the occluded state. To account for this limitation, the “clamp-and-switch” model has recently been proposed (2). This model suggests that the conformational transition process is more dynamic than previously assumed and that the switch between conformations is driven by pore-lining helices that tend to form the occluded state and that allow for outward-facing to inward-facing rotations and vice versa.

Inorganic phosphate (P\(_i\)) is required for numerous cellular functions, such as synthesis of DNA and membrane lipids, intracellular signaling, and the generation of high-energy phosphate esters in ATP. Because of the central role of P\(_i\), cells have adopted strategies to ensure rapid cellular responses to internal and external fluctuations in P\(_i\) levels that may disturb cellular phosphate homeostasis. Moreover, several P\(_i\) transporters have been shown to transport P\(_i\) by H\(^+\)-coupled symport (4).

Currently, the only available crystal structure of a P\(_i\):H\(^+\) transporter is the eukaryotic *Piriformospora indica* transporter PiPT, which was resolved in the substrate-bound inward-facing occluded conformation (5). The current model for P\(_i\):H\(^+\)-transport is based on this crystal structure and describes three major conformational variations (i.e. substrate-docking, binding, and release) (5). A weakness of this model is that it lacks experimental data on the regulatory residues in each stage of the transport cycle.

The *Saccharomyces cerevisiae* Pho84 high-affinity phosphate transporter is a member of the phosphate:H\(^+\) symporter family (2.A.1.9) and is the main transporter during P\(_i\)-limiting condi-

...findings. Furthermore, Pho84 activates the protein kinase A (PKA) pathway, which senses and signals the uptake of external P<sub>i</sub> in phosphate-starved cells. This dual functionality of Pho84 has led to its classification as a transceptor (6). A three-dimensional model of Pho84 in the open inward-facing conformation has been created by homology modeling using the glycerol 3-phosphate transporter GlpT as a template (7). This model has been used to verify the roles of key residues in P<sub>i</sub> binding, transport, and signaling (8). A comparison of the Pho84 and PiPT structures revealed a series of conserved residues in the P<sub>i</sub> binding site (5), and both the N and C termini of Pho84 are not in the binding site of the open inward-facing conformation. This difference may result from protonation/deprotonation of the nearby Asp<sup>178</sup> residue (Asp<sup>149</sup> in PiPT), which may affect the active conformation of the transporter. In addition, Asp<sup>178</sup> has been shown to participate in H<sup>+</sup>-transfer (8).

Nevertheless, the protonation/deprotonation mechanism of regulating conformational changes in P<sub>i</sub>;H<sup>+</sup> transporters remains putative.

In this study, we examined the role of Tyr<sup>179</sup> on the P<sub>i</sub> release step in the open inward-facing conformation of Pho84. To address the finer details of the release mechanism and to build on the transport model previously suggested for PiPT, we performed a series of unrestrained molecular dynamics (MD) and steered molecular dynamics (SMD) simulations using different protonation states of P<sub>i</sub> and Asp<sup>178</sup>. These simulations revealed that the protonation state of Asp<sup>178</sup> alters the conformational state of Pho84. Upon protonation of Asp<sup>178</sup>, Tyr<sup>179</sup> underwent a rotamer change to become part of the binding site. This agrees with the contact found between P<sub>i</sub> and Tyr<sup>150</sup> in the PiPT occluded inward-facing conformation. Based on SMD simulations, different P<sub>i</sub> release routes were suggested. The lowest-energy release route was found with H<sub>2</sub>P<sub>4</sub> and deprotonated Asp<sup>178</sup>.

We also confirmed the importance of Tyr<sup>179</sup> in regulating P<sub>i</sub> transport by a series of site-directed mutagenesis studies and biochemical assays. Finally, we measured trehalase activity to determine whether Tyr<sup>179</sup> regulated PKA signaling, and we demonstrated that the release of P<sub>i</sub> is critical for signaling. Altogether, our data contributes to a more complete picture of the dual functions of phosphate transceptors.

Results and Discussion

**Tyr<sup>179</sup> Is Crucial for the Substrate Release Step of P<sub>i</sub> Transport**—The two-dimensional topology of Pho84 consists of a C-domain and an N-domain, each domain is made up of six transmembrane segments (Table 1), and both the N and C termini are oriented toward the cytoplasm. The three-dimensional *in silico* model displays a Mayan temple shape (3) (Fig. 1A) with a distinct N- and C-terminal domain organization and a clearly visible transport channel in the center of the protein (Fig. 1B). The transport channel is a structural feature common in MFS proteins.

A multiple sequence alignment (MSA) analysis of Pho84 with other P<sub>i</sub>;H<sup>+</sup> transporters revealed that Tyr<sup>179</sup> is highly conserved (Fig. 2). Furthermore, the corresponding Tyr<sup>150</sup> is proposed to be in the P<sub>i</sub> binding site of the PiPT crystal structure. In the inward-open conformation of the Pho84 model, Tyr<sup>179</sup> orients toward the cytoplasm and points away from the binding cavity. A growth spot test with strains expressing mutant alleles...
of PHO84 was performed to assess changes in the transport activity of Pho84 (Fig. 3). When compared with the wild-type strain (CEN.PK 113–7D PHO84-6xHis-2xmyc), the strains expressing Pho84 Tyr179-Ala and Tyr179-Gly exhibited drastic reductions in growth in low-Pi (LPi) conditions indicating that Tyr179 is crucial for transport. The growth of the strains expressing Pho84 Tyr179-Ser and Tyr179-Phe was equivalent to the growth of the Pho84 wild-type strain. In addition, in vivo radiolabeled Pi uptake assays showed a drastic reduction in transport activity in the Tyr179-Ala mutant and abolished activity in the Tyr179-Gly mutant (Fig. 4A). The Tyr179-Ser and Tyr179-Phe mutant strains had uptake activities equivalent to the uptake activity in the Pho84 wild-type strain. Immunoblot analysis confirmed that the site-directed mutations yielded full-length recombinant proteins (Fig. 4B).

Furthermore, expression of a functional Pho84 transporter is required to suppress the repressible acid phosphatase (rAPase) activity of PHO5, the major acidic phosphatase (9). A loss-of-function strain, pho84/H9004, results in constitutive expression of PHO5 independent of the external Pi conditions (Fig. 5). The wild-type strain was analyzed under either high-Pi (HPi) or low-Pi (LPi) conditions (8) revealing reduced and elevated secreted phosphatase activity, respectively. Strains expressing Pho84 Tyr179-Ala and Tyr179-Gly exhibited pronounced increases in secreted phosphatase activity, which is consistent with the significantly reduced transport activities of these mutants. Strains expressing Pho84 Tyr179-Ser and Tyr179-Phe had secreted phosphatase activities similar to the wild-type level. These results show that full-length expressed, plasma membrane localized, non-functional Pho84 suppresses rAPase activity resulting in less activity relative to the activity in pho84/H9004 (9).

Our data for Tyr179 clearly shows that this residue plays a crucial role in Pi transport. By introducing a side chain that is relatively inert, such as a residue that is non-charged, weakly polar, or lacking an aromatic residue, transport activity was largely abolished. In contrast, by introducing side chains with...
increased polarity (Tyr¹⁷⁹→Ser) or hydrophobicity (Tyr¹⁷⁹→Phe), transport activity was restored to the wild-type level.

**Protonation/Deprotonation of Asp¹⁷⁸ and Its Impact on Pi Release**—A protonation/deprotonation cycle has been shown to be crucial for the functionality of many transporters. The *Escherichia coli* lactose permease LacY serves as a paradigm for understanding the importance of protonation/deprotonation in the transport cycle that begins in the outward-open conformation and requires functional protonation to facilitate substrate binding (10). MD simulations of the protonation/deprotonation of Glu³²⁵ showed significant changes in the structure leading to a transition from the inward-facing to the occluded conformation (11). MD simulations of the *E. coli* sugar fucose:H⁺ symporter FucP also showed that protonation of Glu¹³⁵ is required to trigger conversion from the outward-open to the inward-open conformation (12). These examples show that protonation/deprotonation events are crucial to the alternating-access dynamics of MFS transporters.

In a previous site-directed mutagenesis study, the Pho84 residue Asp¹⁷⁸ was mutated to Glu and Asn, and Asn was found to mimic a protonated aspartate (8). These results led to the hypothesis that protonation of Asp¹⁷⁸ plays a role in a late phosphate release step of the transport cycle. To investigate this hypothesis, a series of unrestrained MD simulations were performed on Pho84 models with protonated or deprotonated Asp¹⁷⁸. Pi was inserted in the Pho84 binding site at approximately equal distances from Lys⁴⁹² and Asp¹⁷⁸. This allowed us to investigate the roles of these residues on Pi binding and on proton transfer. In addition, simulations were conducted using different protonation states of Pi (H₃PO₄, H₂PO₄⁻, and HPO₄²⁻) to resolve the role of charge balance in the binding site and its influence on the energetics of cytosolic release of Pi (see supplemental Table S1 for information on the number of molecules in each system and the denotations that are used throughout this paper). All of the systems were subsequently subjected to 30 ns of equilibration to reach stable energy, temperature, and density values (supplemental Figs. S1–S16). Equilibration of the transmembrane helices (Fig. 1) in the 1-palmitoyl-2-oleoyl-sn-glycero-3-phosphocholine bilayer were verified by recording root mean square deviation values over time for

Mechanistic Studies on the Pho84 Transporter

The largest shift in the distance between Asp\(^{178}\) and Asp\(^{76}\) upon protonation of Asp\(^{178}\) was observed for H\(_2\)PO\(_4\)\(^-\) rather than for HPO\(_4\)\(^2-\). SMD simulations with H\(_2\)PO\(_4\)\(^-\) in the binding site and protonated Asp\(^{178}\) resulted in a helical rotation that affected helices I and IV such that Asp\(^{76}\), rather than Asp\(^{178}\), bound to P\(_i\) (Fig. 6, A2, and supplemental Fig. S18). These data demonstrate that the charge distribution in the Pho84 binding site regulates the active conformational state of Pho84.

In addition to the observed roles of Asp\(^{178}\) in regulating P\(_i\) binding and proton-coupling, the change in the conformational state of helix IV in Pho84 that occurred upon protonation of Asp\(^{178}\) led to Tyr\(^{179}\) becoming more accessible for P\(_i\) binding (Fig. 6, B2 and C2, and supplemental Fig. S20). X-ray crystallographic analysis of PiPT in the substrate-bound inward-facing occluded conformation shows that the corresponding tyrosine (Tyr\(^{159}\)) is involved in P\(_i\) binding (5). As shown in a comparison of Fig. 6, panels A1/A2 versus panels B1/B2/C1/C2, the shift in the position of Tyr\(^{179}\) as correlated to the protonation state of Asp\(^{178}\) was not as prominent for models that incorporated H\(_2\)PO\(_4\)\(^-\).

We investigated the stability of salt bridges involving Asp\(^{76}\) and Asp\(^{79}\) and their link to Pho84 conformational changes (Fig. 6). We found stable contacts between Asp\(^{76}\)-Arg\(^{267}\) and Asp\(^{79}\)-Arg\(^{168}\) in all of the simulations with the exception of the model incorporating H\(_2\)PO\(_4\)\(^-\) and protonated Asp\(^{178}\) in which Asp\(^{76}\) and Asp\(^{79}\) exchanged positions (Fig. 6, A2). Moreover, a Pho84 simulation without P\(_i\) in the binding site showed a disruption of the Asp\(^{79}\)-Arg\(^{168}\) salt bridge after 15 ns of equilibration. Because protonation of Asp\(^{178}\) led to a stable Asp\(^{79}\)-Arg\(^{168}\) salt bridge, we suggest that the presence of P\(_i\) in the binding site may increase the conformational stability of Pho84 (data not shown).

Characterizing Alternative Release Routes Using SMD Simulations—A series of SMD simulations were performed to investigate alternative P\(_i\) release routes in Pho84. For each model investigated, five separate SMD simulations were performed to sample the configurational space provided by the flexible Lys\(^{492}\) residue and to identify possible Pho84 exit routes using various protonation states of both Asp\(^{178}\) and P\(_i\). Although, according to the Jarzynski equality method that requires a large number of samplings to be performed (14–16),
Mechanistic Studies on the Pho84 Transporter

A proposed mechanism for the release step in \( \text{P}_2\text{H}^+ \) transporters using Pho84 as a model system. Snapshots representing the inward-facing open (image on the left) and occluded (image on the right) conformational states of Pho84 after simulating protonated (Asp\(^{178}\)-H) or deprotonated states (Asp\(^{178}\)) of Asp\(^{178}\). Detailed views of the binding site (helices are represented as gray cylinders) in both conformational states of Pho84 clearly show \( \text{H}_2\text{PO}_4^- \) in the binding site and residue Tyr\(^{179}\) either oriented away from the binding site (Asp\(^{178}\)) or toward the binding site (Asp\(^{178}\)-H). The structures shown were obtained after 3.5 ns of steered MD simulations and multiple superimposed structures of P\(_i\) (van der Waals representation, extracted every 0.175 ns). Moreover, the N (transmembrane helices I-VI) and C (transmembrane helices VII-XII) domains of Pho84 are shown as blue and orange van der Waals representations, respectively. The connecting loop between these domains, L-VI, is shown as a gray schematic representation.

The Proposed Mechanism for \( \text{P}_i \) Release in \( \text{P}_2\text{H}^+ \) Transporters

Using Pho84 as a Model—Results from unrestrained and steered MD simulations showed that the protonation states of P\(_i\) and Asp\(^{178}\) and the resulting orientations of Tyr\(^{179}\) impact regulation of the P\(_i\) release pathway. Protonation of Asp\(^{178}\) is a crucial step in triggering the conformational change of Pho84 from an open inward-facing conformation to a more occluded conformation. However, this switch in conformation appears to be independent of the protonation state of P\(_i\). As a result of Pho84 adopting the occluded conformation, Tyr\(^{179}\) becomes part of the binding site as seen in the PiPT crystal structure.

Based on our observations, we propose a sequential mechanism for the release of P\(_i\) (Fig. 8).

(i) The open inward-facing conformation of Pho84 containing deprotonated Asp\(^{178}\) is the active form that releases P\(_i\). We found that \( \text{H}_2\text{PO}_4^- \) is the most favorable protonation state of P\(_i\) to be released due to the distribution of the charges of the residues along the release pathway. In this active conformation of Pho84, Tyr\(^{179}\) points away from the binding site and may regulate the possible \( \text{H}_2\text{PO}_4^- \) release routes and/or may act as a gatekeeper, which blocks more hydrophobic phosphate substrates.

(ii) Protonation of Asp\(^{178}\) results in a conformational change from an open inward-facing conformation to an occluded con-

FIGURE 7. Representative data from steered dynamics simulations for the release of P\(_i\) from the Pho84 binding site after initially restraining the Lys\(^{992}\)-P\(_i\) distance for 0.1 ns. The calculated force profiles and the Pho84 residues (and their transmembrane helix) that form hydrogen bonds with P\(_i\) along the release pathway or the average number of hydrogen bonds formed with water along the route for models involving deprotonated and protonated Asp\(^{178}\). The Proposed Mechanism for \( \text{P}_i \) Release in \( \text{P}_2\text{H}^+ \) Transporters

Using Pho84 as a Model—Results from unrestrained and steered MD simulations showed that the protonation states of P\(_i\) and Asp\(^{178}\) and the resulting orientations of Tyr\(^{179}\) impact regulation of the P\(_i\) release pathway. Protonation of Asp\(^{178}\) is a crucial step in triggering the conformational change of Pho84 from an open inward-facing conformation to a more occluded conformation. However, this switch in conformation appears to be independent of the protonation state of P\(_i\). As a result of Pho84 adopting the occluded conformation, Tyr\(^{179}\) becomes part of the binding site as seen in the PiPT crystal structure.

Based on our observations, we propose a sequential mechanism for the release of P\(_i\) (Fig. 8).

(i) The open inward-facing conformation of Pho84 containing deprotonated Asp\(^{178}\) is the active form that releases P\(_i\). We found that \( \text{H}_2\text{PO}_4^- \) is the most favorable protonation state of P\(_i\) to be released due to the distribution of the charges of the residues along the release pathway. In this active conformation of Pho84, Tyr\(^{179}\) points away from the binding site and may regulate the possible \( \text{H}_2\text{PO}_4^- \) release routes and/or may act as a gatekeeper, which blocks more hydrophobic phosphate substrates.

(ii) Protonation of Asp\(^{178}\) results in a conformational change from an open inward-facing conformation to an occluded con-

FIGURE 7. Representative data from steered dynamics simulations for the release of P\(_i\) from the Pho84 binding site after initially restraining the Lys\(^{992}\)-P\(_i\) distance for 0.1 ns. The calculated force profiles and the Pho84 residues (and their transmembrane helix) that form hydrogen bonds with P\(_i\) along the release pathway or the average number of hydrogen bonds formed with water along the route for models involving deprotonated and protonated Asp\(^{178}\). Numbers in brackets represent hydrogen bonding between the residue and H\(_2\text{PO}_4^-\) as a percentage of the total simulation time.

FIGURE 8. A proposed mechanism for the release step in \( \text{P}_2\text{H}^+ \) transporters using Pho84 as a model system. Snapshots representing the inward-facing open (image on the left) and occluded (image on the right) conformational states of Pho84 after simulating protonated (Asp\(^{178}\)-H) or deprotonated states (Asp\(^{178}\)) of Asp\(^{178}\). Detailed views of the binding site (helices are represented as gray cylinders) in both conformational states of Pho84 clearly show \( \text{H}_2\text{PO}_4^- \) in the binding site and residue Tyr\(^{179}\) either oriented away from the binding site (Asp\(^{178}\)) or toward the binding site (Asp\(^{178}\)-H). The structures shown were obtained after 3.5 ns of steered MD simulations and multiple superimposed structures of P\(_i\) (van der Waals representation, extracted every 0.175 ns). Moreover, the N (transmembrane helices I-VI) and C (transmembrane helices VII-XII) domains of Pho84 are shown as blue and orange van der Waals representations, respectively. The connecting loop between these domains, L-VI, is shown as a gray schematic representation.
Mechanistic Studies on the Pho84 Transporter

formation in which Tyr\textsuperscript{179} is reoriented into the binding site and Pho84 is locked into a closed and inactive conformation, which is unable to release $\mathrm{H}_2\mathrm{PO}_4^-$. 

Transceptor Function Is Coupled to the Transport Cycle—In addition to its well known transport function, the Pho84 transceptor has the unique property of PKA signaling (17, 18). Previous point mutation studies have shown that these functions can be uncoupled resulting in a non-transporting protein that is still able to activate PKA upon phosphate detection (8). These studies focused on mutating residues that bind $\mathrm{P}$, or that could bind phosphate analogues that trigger PKA activation. In this study, we addressed whether limited release of $\mathrm{P}$, from the Pho84 binding site influenced the ability of Pho84 to activate PKA (Fig. 9). Because transport activity data clearly showed that Tyr\textsuperscript{179} is crucial for Pho84 functionality, trehalase activity assays were performed with relevant mutants.

The ability of the Tyr\textsuperscript{179}-Ala mutant strain to activate PKA was slightly reduced, whereas the ability of the Tyr\textsuperscript{179}-Gly mutant strain to activate PKA was abolished. The Tyr\textsuperscript{179}-Phe and Tyr\textsuperscript{179}-Ser mutant strains were able to activate PKA equivalent to the wild-type strain. Modest to strong reductions in transport activity in Asp\textsuperscript{178} and Asp\textsuperscript{358} mutants, respectively, were shown to not affect signaling. Abolishing transport by introducing an Asp\textsuperscript{358}-Glu mutation resulted in a 50% reduction in signaling capacity (8). These observations show that, although transport and signaling are tightly intertwined, there are subtle yet profound differences in the residues that regulate the dual functions of Pho84 (Table 2).

In this study, we showed that Tyr\textsuperscript{179}, which is associated with the substrate release step during transport, has a stronger influence on signaling than Asp\textsuperscript{358} (Table 2), which has been shown to be crucial for substrate binding (8). We hypothesize that this difference originates from the different phosphate binding and release mechanisms operating in transport and in signaling.

Experimental Procedures

Materials and Strains—[\textsuperscript{32}P]Orthophosphate (carrier-free) was obtained from PerkinElmer Life Sciences. Anti-Myc-HRP antibodies were obtained from Life Technologies Invitrogen (The Netherlands). Anti-actin-HRP antibodies were obtained from Abcam (UK). All other reagent grade materials were obtained from commercial sources. Haploid, prototrophic \textit{S. cerevisiae} CEN.PK 113–7D (MATa MAL2–8c SUC2) was kindly provided by P. Kötter (Frankfurt, Germany).

Sequence Conservation Analysis—Functionally important amino acid residues in the Pho84 primary amino acid sequence were identified by performing a conservation analysis based on MSA using multiple sequence comparison by log-expectation (MUSCLE) alignment software (19). Pho84 homologues were obtained from a BLAST search of the UniProt database. Sequences representative of fungi and plants were selected. The Swiss-Prot protein sequences were retrieved from the NCBI Protein server (www.ncbi.nlm.nih.gov/protein/). The selected species and their accession numbers are \textit{S. cerevisiae} Pho84 (P25297), \textit{P. indica} (A8N031), \textit{Arabidopsis thaliana} Phit1-1 (Q8VYM2), \textit{A. thaliana} Phit 1–2 (Q96243), \textit{Oryza sativa} (Q8G59H), \textit{Hordeum vulgare} (Q8HE60), \textit{Medicago truncatula} (Q8GS4G), \textit{Glomus intraradices} (Q96VN6), \textit{Glomus versiforme} (Q00908), and \textit{Pholiota nameko} (Q96X52) (Fig. 2). The MSA figure was created using CLC Workbench (CLC Bio-Qiagen, Aarhus, Denmark). The Tyr\textsuperscript{179} residue was mapped onto the three-dimensional \textit{in silico} Pho84 model (available at PMDB website, ID PM0076296). All of the figures were created using either PyMOL (Molecular Graphics System, version 1.3, Schrödinger, LLC.) or Visual Molecular Dynamics (VMD, version 1.9.1, University of Illinois at Urbana-Champaign, IL) (20).

Strain Construction—Mutants were created by oligonucleotide-directed site-specific mutagenesis using a plasmid containing the \textit{PHO84} WT gene as described previously (8). The synthetic oligonucleotides used are listed in Table 3. The mutagenesis was performed using the Stratagene (USA) QuikChange\textsuperscript{TM} II mutagenesis kit according to the manufacturer’s protocol. All of the mutant constructs were confirmed by DNA sequencing the entire \textit{PHO84} WT gene. Using pU6H2MYC/\textit{PHO84} WT and pU6H2MYC/\textit{PHO84} MUT as templates for PCR, cassettes containing the last 1.3 kb of \textit{PHO84} WT or \textit{PHO84} MUT, c-myc, a His\textsubscript{6} epitope, and a selection (Kan\textsuperscript{r}) marker were transformed into CEN.PK 113–7D and were incorporated into the genome by homologous recombination.

| Amino acid | Transport | Sensing/signaling |

Positive transformants were selected on YPD-G418 (200 μg ml<sup>−1</sup>) plates. Resistant colonies were re-streaked onto fresh YPD-G418 (200 μg ml<sup>−1</sup>) plates and were verified by PCR, sequencing, and immunoblot analysis.

**Growth Conditions**—Cells expressing Pho84<sup>WT</sup>-myc or Pho84<sup>MUT</sup>-myc were precultivated aerobically for 12 h in YPD medium (transformed cells were kept in the presence of 200 μg ml<sup>−1</sup> G418) at 30 °C under continuous agitation, washed twice, and inoculated in synthetic complete (SC) high phosphate (HP, 10 mM KH₂PO₄) or low phosphate (LP, 200 μM KH₂PO₄) media supplemented with 2% glucose. Cells in LP conditions were grown aerobically at 30 °C with shaking at 200 rpm for 6 h. Samples were withdrawn at the indicated time points for further phosphate assay and Western blotting analyses.

**Yeast Growth Spot Tests**—Strains were cultured overnight in YPD at 30 °C under continuous agitation. Cells were collected, washed twice with sterile dH₂O, and resuspended in sterile dH₂O at an A<sub>600</sub> of 0.3. A × 10 dilution series was spotted onto HP and LP SC medium agar plates. The plates were incubated at 30 °C, and growth was recorded every 24 h for a total of 3 days. To visualize the reduction in growth of the pho84Δ and mutant strains under LP conditions, images were acquired with a higher illumination setting resulting in a brighter background. The figures were cropped and no further image processing was applied.

**Phosphate Transport Measurements**—Phosphate uptake in intact *S. cerevisiae* cells expressing Pho84<sup>WT</sup>-myc or Pho84<sup>MUT</sup>-myc was measured as previously described (8). Briefly, cells were grown in LP, medium and assayed by addition of 2 μl of [³²P]orthophosphate (carrier-free, 0.18 Ci μmol<sup>−1</sup>; 1 mCi = 37 MBq) (PerkinElmer, USA) and phosphate (10 mM KH₂PO₄) to a final concentration of 220 μM. To determine total transport activity, a final phosphate concentration of 110 μM was used. Cells were resuspended to 1 mg ml<sup>−1</sup> (wet weight) in buffer containing 25 mM Tris succinate, pH 4.5, and 3% glucose. Aliquots of 30 μl were incubated for 10 min at room temperature. After 10 min, 3 ml of ice-cold 25 mM Tris succinate, pH 4.5, buffer was added to stop the reaction. The cells were rapidly filtered (Whatman GF/F, USA) and the radioactivity retained on the filters was measured by liquid scintillation spectrometry.

**Immunoblot Analysis of Pho84 Expression**—Immunoblot analysis was performed as previously described (8). Briefly, membrane fractions were collected and 10 μg of protein samples were separated by SDS-PAGE using a 10% Laemmli system (21). Anti-myc HRP-conjugated antibody (anti-myc-HRP, 1:5000, Novex®) was used to detect expression of the Pho84<sup>WT</sup>mut-myc constructs. The (−) control was cut from the blot to avoid visualization of irrelevant samples, but detection was performed simultaneously with the mutant sample blot. As a loading control, 10 μg of total cell extract was loaded onto a separate gel according to the previously described protocol, and anti-β-actin HRP-conjugated antibody (1:5000) (Abcam, UK) was used for detection. After 1 min of incubation with chemiluminescent substrate (GE Healthcare, UK), the membrane-enriched sample blot was exposed to X-ray film for 1.5 min. The control blot was visualized using the Bio-Rad ChemiDoc™ MP imaging system with an exposure time of 30 s. The molecular masses of the separated proteins were determined by their mobility relative to the pre-stained protein markers (Fermentas, Germany). Figures were cropped and no further image processing was applied.

**Acid Phosphatase Assays**—The rAPase activity was assayed in liquid using an adapted protocol for the colorimetric Abcam® Acid Phosphatase Assay Kit. Briefly, whole cells were used as the source of the enzyme and p-nitrophenyl phosphate was used as the substrate. Yeast strains were grown overnight in 5 ml of YPD at 30 °C, centrifuged, and washed twice with LP, SC medium. Washed cells were inoculated into 15 ml of LP, or HP, phosphate SC medium to an A<sub>600</sub> of 0.4. Cells were grown at 30 °C under continuous agitation for 3 h after which 80 μl of the cell suspension was harvested, washed once with acetate buffer (60 mM, pH 4.5), and resuspended in 80 μl of acetate buffer containing 1 mM p-nitrophenyl phosphate (final concentration). The reaction was incubated at 25 °C for 1 h and was then stopped with the addition of 20 μl of saturated Na₂CO₃. The cells were removed from the reaction by centrifugation before measuring the A<sub>405</sub>. The relative rAPase activity was determined by the formula A<sub>405</sub>/A<sub>600</sub> × t, in which t is the time of incubation (min).

**Trehalase Activity Measurements**—Cells were cultured at 30 °C to exponential phase (A<sub>600</sub> = 1.0–1.5) in YP medium with 2% (w/v) glucose. Mid-exponential phase cells were harvested and transferred to phosphate starvation medium (5.7 g liter<sup>−1</sup> YNB without phosphate, with ammonium sulfate) with 4% (w/v) glucose and appropriate auxotrophic supplements. Cells were starved of phosphate for 3 days at 30 °C under continuous shaking, and starvation medium was refreshed daily. The phosphate-starved glucose-repressed cells were rapidly cooled on ice and harvested by centrifugation (5000 × g for 5 min at 4 °C). The pellet was washed twice with ice-cold 25 mM MES buffer, pH 6.0, resuspended in phosphate starvation medium with 4% (w/v) glucose, and incubated at 30 °C with shaking. After 30 min of incubation, 1 mM KH₂PO₄ was added to the culture. 75 mg ml<sup>−1</sup> cell samples were taken at the indicated time points. Cells were rapidly cooled by the addition of ice-cold dH₂O, centrifuged (5000 × g for 5 min at 4 °C), and re-suspended in 0.5 ml of ice-cold 25 mM MES buffer, pH 7.0. Crude cell extracts were prepared as described previously (22) and dialyzed (BRL microdialysis system) against 25 mM MES buffer, pH 7.0, with 50 μM CaCl₂ at 4 °C. Trehalase activity in the dialyzed cell extracts was determined using a coupled enzymatic reaction of glucose oxidase and peroxidase with glucose as described previously (22). The specific activity was expressed as nanomole of glucose liberated per min per mg of protein. The total amount of protein in the samples was determined using the standard Lowry method described previously (23).
Mechanistic Studies on the Pho84 Transporter

Computational Section—An inward-facing open conformation of Pho84 from *S. cerevisiae* was obtained by structurally fitting (7) it to the helix containing the transmembrane region (TM-I–XII, Table 1) in the crystal structure of the glycerol 3-phosphate/phosphate antiporter GlpT (24) from *E. coli*. This conformation was used as the starting conformation for the series of MD simulations performed in this work. After performing primary structural alignments between Pho84 (587 amino acids) and GlpT, the N- and C-terminal extensions of Pho84 could not be modeled onto the GlpT structure that contains only 452 amino acids. Hence, we decided not to include the regions of Pho84 (amino acids 1–54 and 552–587) that we could not structurally model in these studies. It must, however, be noted that these regions of Pho84 may be important for biological function and will be the target of future studies.

To investigate the role of proton transfer on translocation of Pᵢ by Pho84, simulations were performed after protonating Asp178, which was previously suggested (8) to participate in Pᵢ by Pho84, simulations were performed after protonating biological function and will be the target of future studies. It could not structurally model in these studies. It must, however, be noted that these regions of Pho84 may be important for biological function and will be the target of future studies.

To investigate the role of proton transfer on translocation of Pᵢ by Pho84, simulations were performed after protonating Asp178, which was previously suggested (8) to participate in Pᵢ by Pho84, simulations were performed after protonating biological function and will be the target of future studies. It could not structurally model in these studies. It must, however, be noted that these regions of Pho84 may be important for biological function and will be the target of future studies.

Steered Molecular Dynamics Simulations—To study the cytosolic release of Pᵢ from the inward-facing open conformation of Pho84, constant velocity steered MD (14) was used to obtain potential release pathways and their respective work profiles. Initially, equilibration at NPT (1 bar, 310 K) and a restraint of 500.0 kcal mol⁻¹ Å⁻² was imposed on the distance between the phosphorus atom of Pᵢ and the e-amino nitrogen of Lys⁴⁹², which set the distance 0.2 Å shorter than the equilibrated distance found after 30 ns of unrestrained simulation. To investigate how the residual motion of the restrained Lys⁴⁹²-Pᵢ pair and the overall dynamics of Pho84 affect the various cytosolic release pathways, five individual simulations were conducted for each system after initially restraining the Lys⁴⁹²-Pᵢ distance for 0.1, 0.2, 0.5, 1.0, or 5.0 ns as described previously. Numerous constant velocity steered MD simulations were then performed using a moving harmonic potential with a spring constant of 5.68 kcal mol⁻¹ Å⁻² applied to the distance. The total extended distance studied in each simulation was 35 Å in which the atomic coordinates and forces were saved every 1 ps. Although, in principle, a steered MD simulation can be considered analogous to a single-molecule atomic force microscopy experiment, the pulling velocity commonly employed is typically several orders of magnitude faster, thus it is difficult to make direct comparisons between calculated ligand pulling work profiles using these techniques (38). Typically, constant velocity steered MD simulations have utilized different pulling velocities to optimize the conditions under which the ligand experiences amino acid contacts on the
Mechanistic Studies on the Pho84 Transporter

Author Contributions—D. S. and J. V. d. V. performed the site-directed mutagenesis, phosphate uptake assays, acid phosphatase activity studies, and the spot tests. G. V. Z. performed the trehalase activity measurements. B. C. G. K. performed all of the theoretical calculations and analyses. B. C. G. K., D. S., and B. P. conceived the idea and the experimental design of the project. B. C. G. K. and D. S. led the writing of this paper. All of the authors have taken part in the preparation of this manuscript, have reviewed the results, and have approved the final version of this manuscript.

Acknowledgments—Simulations were performed on resources provided by the Swedish National Infrastructure for Computing (SNIC) at Lunarc-Alarik/Aurora (Dnr: 2014/1–404/2015–1–444, Biophysics of Cellular Transport).
