Whilst accumulating reports have shown the beneficial effects of coffee against chronic liver diseases, the effects of coffee against fatty liver have not yet been reported. In this cross-sectional and the follow-up studies, we investigated the effects of coffee on the production of fatty liver in healthy males, using ultrasonography. In the follow-up study, annual changes in daily coffee intake during the 5-year study period were compared between subjects who appeared to have fatty liver (fatty liver group) and those who did not appear to have fatty liver (non-fatty liver group) in the matched study according to age, body mass index (BMI) and daily exercise level. The effects of changes in daily coffee intake between both groups on the development of fatty liver were investigated after adjustments for related factors, such as BMI, daily coffee and alcohol intake and exercise level. In the cross-sectional study, the subjects with fatty liver were revealed to have a lower daily coffee intake than those without fatty liver. In the follow-up study, a significant difference in the changes in daily coffee intake was observed between the fatty liver and non-fatty liver groups with a decrease in daily coffee intake observed in the former group, compared with the change in the latter group. Further, daily coffee intake was negatively correlated with the development of fatty liver after adjustments for related factors. These findings suggest a protective effect of coffee against fatty liver.

INTRODUCTION

The prevalence of lifestyle-related diseases has been increasing in Japan as a result of dietary changes, such as an increase in the composition of saturated fatty acids and alcoholic beverages and lifestyles that lead to the neglect of one’s health. In response to this prevalence of lifestyle-related diseases, the number of cases with fatty liver is also escalating. Since liver dysfunction, most cases of which are thought to be caused by fatty liver, is observed very frequently in combination with obesity in annual health check-ups, fatty liver is considered to be a component of, or at least a predictor of, metabolic syndrome.

Accumulating reports have shown the beneficial effects of coffee on liver function. Epidemiologic surveys from the last 20 years have found an association between higher coffee consumption and lower levels of liver enzymes and a low risk of chronic liver diseases, including cirrhosis or hepatocellular carcinoma. However, the beneficial effects of coffee against fatty liver have not yet been determined. In the present cross-sectional and follow-up studies, we investigated the effects of coffee on the development of fatty liver in men attending serial annual health examinations.
A logistic regression analysis after adjustments for age, BMI, exercise level, daily coffee and alcohol intake in 1999 or 2004, and such factors as daily coffee, green tea and alcohol intake; smoking index, and biochemical function. Changes in daily coffee intake over the 5-year study period were compared between the two groups using a two-way repeated measures analysis of variance (ANOVA). The effects of changes in daily coffee intake difference over the 5-year study period were compared between the fatty liver and the non-fatty liver groups using a logistic regression analysis after adjustments for age, BMI, and daily coffee and alcohol intake in 2004; the subjects from those without fatty liver were randomly selected from amongst those subjects that met the matching criteria. A total of 492 males, consisting of the 164 males from those with fatty liver (fatty liver group) and 328 males from those without fatty liver (non-fatty liver group), were examined in this study. Serial changes in daily coffee intake from 1999 to 2004 were compared between these two matched groups. Further, the effect of changes in daily coffee intake over the 5-years study period on the development of fatty liver in these groups was investigated after adjustments for age, BMI, exercise level, daily coffee and alcohol intake in 2004, and differences in BMI, exercise level and daily alcohol intake over the 5-year study period.

Data Analysis —— Unpaired t-tests were used to analyze the correlations between the development of fatty liver and age; BMI; exercise level; coffee, green tea and alcohol intake; smoking index, and biochemical function. Changes in daily coffee intake over the 5-year study period were also compared between the two groups using a logistic regression analysis after adjustments for age, BMI, and daily coffee and alcohol intake in 2004 as well as differences in BMI, exercise level, and daily alcohol intake over the 5-year study period. All p-values were two sided, and the level of
significance was $p < 0.05$.

**RESULTS**

**Cross-sectional Study**

Among the 1612 subjects, 376 (23.3%) exhibited fatty liver in 1999 and 468 (29.0%) exhibited fatty liver in 2004. As of 2004, fatty liver had disappeared in 72 of the 376 cases of fatty liver observed in 1999, but 164 new cases developed amongst the 1236 males without fatty liver in 1999. In both 1999 and 2004, the subjects with fatty liver reported a lower volume of daily coffee intake and exhibited a higher BMI and liver enzyme levels, compared with those without fatty liver (Fig. 1). No significant differences in the mean daily intakes of alcohol and green tea were observed between the two groups, either in 1999 or 2004.

**Follow-up Study for Matched Cases**

The characteristics of the subjects in 1999 and 2004 in the follow-up study for matched cases are shown in Table 1. The mean (± S.D.) ages of the subjects for the non-fatty liver group and fatty liver groups in 2004 were 49.2 ± 7.0 and 49.4 ± 7.6, re-

Fig. 1. Bar Graph Showing Daily Coffee, Green Tea and Alcohol Intake; BMI (the Weight in Kilograms Divided by the Square of the Height in Meters); Exercise Level; and Alanine Aminotransferase Level between Subjects with Fatty Liver and Subjects without Fatty Liver in 1999 and 2004.

Among the 1612 subjects, 376 had fatty liver in 1999 and 468 had fatty liver in 2004. Alcohol intake and exercise level were scored into 5 categories, as mentioned in the text. Data are expressed as mean ± S.E. *$p = 0.06$, **$p < 0.01$, ***$p < 0.001$.
Table 2. Logistic Regression Analysis to Determine the Effects of Changes in Daily Coffee Intake Difference over the 5-year Study Period on the Development of Fatty Liver in the Fatty Liver and the Non-fatty Liver Groups, with Adjustments for Related Factors, in Matched Cases

|                          | Odds Ratio | 95% CI     | p Value |
|--------------------------|------------|------------|---------|
| Age (2004)               | 1.01       | 0.99–1.04  | 0.33    |
| BMI (2004)               | 1.01       | 0.92–1.11  | 0.83    |
| Exercise Level (2004)    | 0.957      | 0.82–1.12  | 0.58    |
| Daily Coffee Intake (2004)| 0.736     | 0.61–0.89  | 0.001   |
| Daily Alcohol Intake (2004)| 0.90      | 0.75–1.08  | 0.26    |
| BMI Difference (2004–1999)| 1.34      | 1.10–1.63  | 0.004   |
| Exercise Level Difference (2004–1999)| 0.96  | 0.83–1.11  | 0.58    |
| Daily Alcohol Intake Difference (2004–1999)| 1.08 | 0.90–1.29  | 0.44    |
| Daily Coffee Intake Difference (2004–1999)| 0.77  | 0.65–0.92  | 0.004   |

A total of 492 subjects without fatty liver in 1999 were divided into the two groups; subjects without fatty liver in 2004 (non-fatty liver group; \( n = 328 \)) and subjects with fatty liver in 2004 (fatty liver group; \( n = 164 \)), matched for age, BMI and exercise level in 2004.

**DISCUSSION**

In Japan, the prevalence of fatty liver is reported to be increasing as 35% in Japanese men and 20% in Japanese women, or about twice the values reported 10 years ago.\(^2,3)\) Many patients with non-alcoholic fatty liver disease (NAFLD) have a long and benign course; others, however, exhibit inflammation and fibrosis and progress to end-stage liver injury, such as cirrhosis, which is called as non-alcoholic steatohepatitis (NASH). NAFLD, including NASH, are now considered to be the hepatic manifestation of the metabolic syndrome.\(^{13,14})\) NASH is estimated to affect 1–3% of Japanese adults and is
considered to become the most important cause of end-stage liver disease.

Centuries of coffee drinking have made it the most consumed beverage in the world. Data on the potential beneficial effects of coffee on liver function and against liver diseases have accrued over the last two decades. Several epidemiologic studies have reported inverse associations of coffee drinking with levels of liver enzymes, as well as with the risk of chronic liver diseases, including liver cirrhosis and even hepatocellular carcinoma. The present epidemiological study revealed, for the first time, that coffee intake may protect against fatty liver. Since the subjects in this study were healthy individuals employed at the same company and maintained a similar lifestyle, including their work and home life, during the 5-year study period, the present results were considered to be relatively reliable. The subjects in this study were limited to only men for the following reasons: first, the average prevalence of fatty liver classified according to sex was reported to be twice as high in men as it was in women in Japan; second, estrogen levels might affect the development of fatty liver in women, since the prevalence of fatty liver increases rapidly in post-menopausal women. In this study, those subjects, who were in therapy with chronic liver diseases, diabetes mellitus and/or hyperlipidemia, were excluded, because the medication to these diseases might influence to the occurrence of fatty liver disease. The diagnosis of fatty liver is usually based on abdominal ultrasonography, which has been established as a simple, reliable and commonly used modality for the clinical screening of fatty liver. Since the ultrasound equipment used to perform the examinations, the radiologists who performed the examinations, and the gastroenterology specialists who made the diagnoses were the same in 1999 and 2004, the differences between the examinations years were thought to be negligible. Since daily coffee intake varied from year to year on an individual basis, we analyzed the data using a two-way repeated measures ANOVA. A significant difference in the changes in daily coffee intake was observed between the fatty liver group and the non-fatty liver group, with a decrease in daily coffee intake observed in the former group, compared with the change in the latter group, suggesting a possible relation between decreased coffee intake and the development of fatty liver. Since the body weight, exercise level, alcohol intake, and the change in body weight, exercise level and alcohol intake over the 5-year study period between the two groups might influence the development of fatty liver, a logistic regression analysis was performed after adjusting for these factors. As a result, the increase in daily coffee intake in the non-fatty liver group, compared with the decrease in daily coffee intake in the fatty liver group, was found to possibly be related to the protection of fatty liver, with a significant odds ratio. Further, whilst increase in the BMI was related to the development of fatty liver, change in alcohol intake was not a significantly independent factor in the development of fatty liver, which is consistent with a previous report based on data obtained from health checkups. Although alcohol is known as an important risk factor of fatty liver, the subjects in this study were unlikely to be heavy drinkers or habitual drinkers, and the effects of alcohol on liver function were thought to be relatively minimal, since they were concerned enough about their health to undergo an annual health check-up.

The presence of steatosis is an important marker of multiorgan insulin resistance. In liver, insulin resistance may be related to alterations in the pathways of uptake, synthesis, degradation, or secretion in hepatic lipid metabolism. Hyperinsulinemia resulting from insulin resistance increases the synthesis of fatty acids in hepatocytes by increasing glycolysis and favours the accumulation of triglycerides within hepatocytes by decreasing the hepatic production of apolipoprotein B-100, with mitochondrial oxidation overload and the production of reactive oxygen species capable of inducing lipid peroxidation of hepatocyte membranes. Coffee contains a vast number of different chemicals, any one of which may be responsible for its protective effects on the liver. Chlorogenic acid and its derivatives contained in coffee are known to be associated with an increase in insulin sensitivities, and to have a strong protective antioxidant effect, which might protect the liver against the accumulation of lipids within hepatocytes. It was reported that caffeine might also improve insulin sensitivity and fatty liver in mice. In addition, coffee and caffeine can cause weight loss, possibly reducing visceral fat and thereby reducing lipid accumulation in hepatocytes. Of all the types of fat tissue, visceral fat is the most metabolically active and which plays an important role in the development of fatty liver. The severity of fatty liver was reported to be positively correlated with visceral fat accumulation, regardless of BMI and excess visceral fat,
when inflamed, has a large effect on insulin sensitivity.33) Recently, a high consumption of caffeine-containing coffee was reportedly associated with a higher adiponectin and lower inflammatory marker concentrations,34) which may play a role in the beneficial effects of coffee on insulin sensitivities and the alleviation of hepatic steatosis.35, 36) However, since other caffeine-containing beverages, such as green tea or cola, failed to demonstrate a significant association between these beverages and a reduction in liver-related endpoints, the mechanisms involved and the substances in coffee that may be responsible for its effect on the liver remain to be elucidated.

A limitation of this study is the lack of information on decaffeinated coffee consumption, brewing method, and variations in cup size and strength. However, because Japanese people usually drink either instant coffee, filtered coffee or canned coffee, the constituents of which are similar to each other, the results in this study were considered to be reliable. Sugar and cream in coffee might have the potential effect on fatty liver, but they were not considered to be a risk factor for fatty liver, since coffee intake in the non-fatty liver group was higher than that in the fatty liver group. Since elevated fat accumulation in the liver was recently reported to be accompanied by atherosclerosis and metabolic syndrome37–39) in a manner that was independent of visceral adiposity,40, 41) the protective effects of coffee against fatty liver may also protect against the development of lifestyle-related diseases. Thus, the possible protective effects of coffee against fatty liver deserve further investigation.
