ABSTRACT
The peculiar velocities of galaxies are an inherently valuable cosmological probe, providing an unbiased estimate of the distribution of matter on scales much larger than the depth of the survey. Much research interest has been motivated by the high dipole moment of our local peculiar velocity field, which suggests a large-scale excess in the matter power spectrum and can appear to be in some tension with the Λ cold dark matter (ΛCDM) model. We use a composite catalogue of 4537 peculiar velocity measurements with a characteristic depth of $33 \ h^{-1} \text{Mpc}$ to estimate the matter power spectrum. We compare the constraints with this method, directly studying the full peculiar velocity catalogue, to results by Macaulay et al., studying minimum variance moments of the velocity field, as calculated by Feldman, Watkins & Hudson. We find good agreement with the ΛCDM model on scales of $k > 0.01 \ h \text{Mpc}^{-1}$. We find an excess of power on scales of $k < 0.01 \ h \text{Mpc}^{-1}$ with a 1σ uncertainty which includes the ΛCDM model. We find that the uncertainty in excess at these scales is larger than an alternative result studying only moments of the velocity field, which is due to the minimum variance weights used to calculate the moments. At small scales, we are able to clearly discriminate between linear and non-linear clustering in simulated peculiar velocity catalogues and find some evidence (although less clear) for linear clustering in the real peculiar velocity data.

Key words: galaxies: kinematics and dynamics – galaxies: statistics – cosmology: observations – cosmology: theory – large-scale structure of Universe.

1 INTRODUCTION AND BACKGROUND
The peculiar velocities of galaxies are a powerful cosmological probe which directly traces the underlying dark matter distribution (independent of galaxy bias) and is also sensitive to scales much larger than the size of the survey. Recent interest in peculiar velocities has been driven by the high dipole moment of our local velocity field, which can appear to be in some tension with the Λ cold dark matter (ΛCDM) model. The ΛCDM model indicates that we should expect a peculiar velocity dipole of magnitude around 100 km s$^{-1}$, although many independent peculiar velocity surveys show evidence for a bulk flow at low redshift of around 400 km s$^{-1}$ in the direction $l = 280°$, $b = 10°$ (Hudson et al. 2004; Watkins et al. 2009; Feldman et al. 2010; Ma, Gordon & Feldman 2011). However, Nusser & Davis (2011) find evidence for a flow more commensurate with ΛCDM of around 260 km s$^{-1}$ (in a similar direction as the other bulk flow results).

In more tension with ΛCDM are significantly higher bulk flows at redshift $\sim 0.25$, which curiously appear to be in the same direction as the low-redshift bulk flows. Abate & Feldman (2012) found evidence for an extremely high bulk flow of around 4000 km s$^{-1}$ at redshift $\sim 0.3$, in a similar direction to other bulk flows. Kashlinsky et al. (2010) find a bulk flow of around 1000 km s$^{-1}$ extending to $z \sim 0.2$ from kinematic Sunyaev–Zel’dovich measurements. If substantiated, these bulk flows would indicate a non-convergence of the peculiar velocity dipole and present a serious challenge to the assumptions of isotropy and homogeneity. However, these bulk flow measurements are far from being as robust as the directly measured peculiar velocity measurements we consider here; Abate & Feldman (2012) note that their result may be entirely due to
systematic effects. In this work, we will only consider the direct peculiar velocity measurements at low redshift.

In addition to the high dipole moment, there also appears to be a low shear of the velocity field (Jaffe & Kaiser 1995; Feldman et al. 2010), which indicates that the density contrast responsible for the velocity dipole is on extremely large scales. At the depths of the peculiar velocity surveys (up to 100 h^{-1} Mpc), this suggests an excess density contrast on scales \sim 1 h^{-1} Gpc. The volume of space probed by galaxy redshift surveys (e.g. Cole et al. 2005; Blake et al. 2010; Reid et al. 2010) is currently too small to robustly constrain clustering on these scales, although Thomas, Abdalla & Lahav (2011) found evidence for excess large-scale power in the MegaZ photometric redshift survey. Measurements of the cosmic microwave background can probe anisotropies on these large scales (Hlozek et al. 2012), although to compare to results at low redshift, the growth of these anisotropies must be assumed, which depends on the cosmological model.

There are many possible explanations for the high dipole moment, ranging from systematic effects to more exotic explanations invoking extended cosmology or modified gravity. Hudson et al. (2004) considered systematic effects in the Streaming Motion of Abell Clusters (SMAC) peculiar velocity survey, such as a dipole variation in the velocity dispersion, galactic extinction and calibration across different observations. They found that systematic effects could account for at most half of the high dipole moment of the SMAC survey, leaving a dipole moment which is still at least three times higher than the \Lambda CDM expectation. There are many theoretical possibilities to extend the \Lambda CDM model to produce a large-scale excess of power and a peculiar velocity dipole, such as modifications to gravity (Ayaita, Weber & Wetterich 2009; Khoury & Wyman 2009), dark energy clustering (Potter & Chongchitnan 2011), vorticity (Palle 2010) or ‘tilted’ universes (Mersini-Houghton & Holman 2009; Kaslinsky et al. 2010; Ma et al. 2011). In this work, we do not address any theoretical explanation in particular, but using the peculiar velocity data to constrain the power spectrum in model-independent band powers, we aim to provide results which will be useful to constrain a range of explanations for the high dipole.

Jaffe & Kaiser (1995), Kolatt et al. (1996), Zaroubi et al. (1997), Kolatt & Dekel (1997), Zaroubi et al. (2001) and Silberman et al. (2001) have used peculiar velocity surveys to infer the matter power spectrum directly at z = 0. More recently in Macaulay et al. (2011), we inferred the underlying power spectrum from moments of the peculiar velocity field from Watkins et al. (2009) and Feldman et al. (2010), specifically in the context of understanding the high bulk flow. One of our main findings was that the excess of power indicated by the anomalously high dipole moment was dramatically reduced when the shear and octupole moments were also included. This leads us to ask if the correspondence with the \Lambda CDM model would be improved if we were to hypothetically include higher still moments of the velocity field. That is the motivation for this work, although we take the approach used by Jaffe & Kaiser (1995) to analyse peculiar velocity catalogues directly, without compressing the data into moments.

Recently, Abate & Erdogdu (2009) applied a similar formalism to constrain the modified gravity parameter \gamma. Similarly, Ma et al. (2011) used a similar formalism to fit for parameters of the dipole moment and velocity dispersion parameter. In both cases, a fiducial \Lambda CDM power spectrum was assumed, and additional parameters of interest were allowed to vary. The key difference between these papers and this work is that here we treat the underlying power spectrum as a set of free parameters, as opposed to fitting extra parameters for additional effects beyond a fixed power spectrum. In this way, we obtain new constraints on the power spectrum which are independent of the fiducial cosmology.

## 2 Method

In this paper, we consider two distinct methods to relate peculiar velocity measurements to large-scale structure: a maximum-likelihood-based approach to analyse a full peculiar velocity catalogue (the ‘catalogue’ method) and an alternative approach studying minimum-variance moments of the velocity field (the ‘moments’ method).

As well as an apparent radial velocity due to the Hubble flow, galaxies also have a peculiar velocity towards local overdensities of matter. This peculiar velocity field \mathbf{v}(r) can be related to the matter density contrast \delta by

$$\mathbf{v}(r) = \frac{f_g H_0}{4\pi} \int d^3r' \delta(r') \frac{(r' - r)}{|r' - r|^{3/2}}. \quad (1)$$

where \(f_g\) is the growth rate of the density contrast, \(\delta \ln \delta / \ln a\), and \(a\) is the scale factor (Peebles 1993). The density contrast is defined in terms of the ratio of the density at \(r, \rho\), to the average density \(\bar{\rho}\), so that \(\delta = \rho / \bar{\rho}\).

We can measure the peculiar velocity via the effect it has on the redshift of the galaxy. The redshift \(z\) of a galaxy is given by a contribution from the Hubble flow, \(H_0 r\), and the line-of-sight component of the peculiar velocity \(S\):

$$cz = H_0 r + S, \quad (2)$$

where, for a galaxy labelled \(m\), at position \(r_m\), we have the line-of-sight peculiar velocity, \(S_m\), given by

$$S_m = r_m \cdot \mathbf{v}(r_m), \quad (3)$$

where \(r_m\) is a unit vector in the direction of galaxy \(m\). To measure \(S\), we thus need to combine the redshift of the galaxy with an independent measure of the distance \(r\). In principle, we can calculate the peculiar velocity of any galaxy for which we have the luminosity distance, measured using distance indicators such as supernovae (SN), Tully–Fisher (TF; Tully & Fisher 1977) or fundamental plane (FP; Dressler et al. 1987) measurements. Individual uncertainties on luminosity distances are typically rather large (5 per cent for SN, and around 10–20 per cent for TF and FP), which propagate to a very large uncertainty in the peculiar velocity.

### 2.1 Maximum likelihood catalogue method

We now consider how to relate a catalogue of peculiar velocity measurements \(S_m\) to large-scale structure, following the method as presented in Jaffe & Kaiser (1995). The method is based on a likelihood framework, where the likelihood \(\mathcal{L}\) is given by

$$\mathcal{L} = \frac{1}{2\pi^2 |\mathbf{R}_{mn}|^2} \exp \left( -\frac{1}{2} \mathbf{S}_m \mathbf{R}^{-1}_{mn} \mathbf{S}_n \right), \quad (4)$$

where \(\mathbf{R}_{mn}\) is the covariance matrix for the peculiar velocity measurements for a catalogue of \(N\) galaxies. The covariance matrix is split into two components, a ‘velocity’ and an ‘error’ term:

$$\mathbf{R}_{mn} = \mathbf{R}^{(v)}_{mn} + \mathbf{R}^{(e)}_{mn}. \quad (5)$$

\(\mathbf{R}^{(v)}_{mn}\) models the coherent large-scale structure, and \(\mathbf{R}^{(e)}_{mn}\) is a noise component to account for non-linear velocity dispersion \(\sigma_v\) and uncertainty in each peculiar velocity measurement \(\sigma_m\). If we assume that the measurement errors are uncorrelated, \(\mathbf{R}^{(e)}_{mn}\) simply
contributes these uncertainties to the diagonal of the covariance matrix and is given by

$$R^\mathrm{(v)}_{mn} = \delta_{mn} \left( \sigma^2_m + \sigma^2_n \right) \delta_{mn},$$

(6)

where $\delta_{mn}$ is a Kronecker delta. This formalism does not include correlations between measurement uncertainties. In principle, there may be small correlations between measurement uncertainties due to, for example, galactic extinction or the assumed mass-to-light ratio within catalogues of the same type of galaxy. However, we assume that the cross-correlations in the data covariance matrix are dominated by the geometry of the survey, which we model with the ‘velocity’ component of the covariance matrix. This term of the covariance matrix contains the power spectrum we are fitting for and is given by

$$R^\mathrm{(v)}_{mn} = \int \frac{4 \pi k^2 \text{d}k}{(2 \pi)^2} P_v(k) f_{mn}(k),$$

(7)

where $P_v(k)$ is the velocity power spectrum, which is related to the matter power spectrum by

$$P_v(k) = \left( \frac{H_0 a}{k} \right)^2 f_g^2 P(k),$$

(8)

where $a$ is the scale factor. The window function $f_{mn}(k)$ is given by

$$f_{mn}(k) = \epsilon_m \epsilon_n \int \frac{d^3 \vec{k}}{4 \pi} \hat{k} \cdot \epsilon(k_m - k_n),$$

(9)

and can be calculated analytically in terms of trigonometric functions. A derivation of $f_{mn}$ is presented in Ma et al. (2011). The general approach we take is to map out the likelihood in terms of parameters of the power spectrum. We next consider an analogous method to analyse moments of the velocity field before considering parametrization of the power spectrum any further, since the parametrization is common to both methods.

### 2.2 Minimum variance moments method

In this paper, we directly compare results between the maximum likelihood catalogue method and an alternative method studying moments of the velocity field, from Macaulay et al. (2011). We can consider the velocity field as a Taylor expansion given by

$$v_i(r) = U_i + U_{ij} r_j + U_{ijk} r_j r_k + \cdots,$$

(10)

where $U_i$ is the dipole moment of the velocity field (often called the ‘bulk flow’) and provides much information about the largest scale fluctuations. $U_{ij}$ is the shear of the velocity field, sensitive to intermediate scales. $U_{ijk}$ is the octupole moment and is sensitive to scales smaller than the size of the survey. The relative sensitivity of each moment is shown in Fig. 1. Since we can only measure the line-of-sight component of each peculiar velocity, each individual measurement must be weighted according to the component of the moment it is sensitive to. Watkins et al. (2009) and Feldman et al. (2010) developed new ‘minimum variance’ weights to estimate the velocity of the volume traced by the galaxies in the survey. These weights are designed to minimize the effects of small-scale motions to provide a better estimate of the large-scale velocities. We do not reproduce the derivations of the weights here; the method is presented in Watkins et al. (2009) for the dipole and extended in Feldman et al. (2010) for the shear and octupole.

With this method, the data consist of the three components of the dipole vector, six independent components of the shear and 10 independent components of the octupole. We take a similar approach as with the catalogue method, splitting the covariance matrix into ‘velocity’ and ‘error’ terms. The ‘velocity’ term is now given by

$$R^\mathrm{(v)}_{pq} = \int \frac{f_g^2}{2 \pi^2} \text{d}k P(k) W^2_{pq}(k),$$

(11)

where $p$ and $q$ index the 19 independent moments. The window function $W^2_{pq}(k)$ is sensitive to different scales for the dipole, shear and octupole, as plotted in Fig. 1. We construct a likelihood in exactly the same manner as the catalogue method, in terms of parameters of a power spectrum, which we now consider.

### 2.3 Power spectrum parametrization

Ultimately, we wish to constrain parameters of the underlying matter power spectrum. There are many choices for ways to parametrize the power spectrum. A popular choice in many earlier works was the power spectrum shape parameter $\Gamma$, the matter density $\Omega_m$ and the power spectrum normalization at $8 \ Mpc \ h$, $\sigma_8$ (Jaffe & Kaiser 1995; Kolatt & Dekel 1995). Silberman et al. (2001) opted for a band-power parametrization, which is the approach we take here, in terms of band powers, $P_a$, so the power spectrum is given by

$$P(k) = \begin{cases} P_a & k_a < k < k_{a+1} \\ 0 & \text{otherwise} \end{cases}$$

(12)

The velocity covariance matrix is then

$$R^\mathrm{(v)}_{mn}(k) \approx \int \frac{(H_0 a)^2 f_g^2}{2 \pi^2} \sum_a P_a \mathcal{K}_a,$$

(13)

where $\mathcal{K}_a$ is given by

$$\mathcal{K}_a = \int_{k_a}^{k_{a+1}} \text{d}k f_m(k).$$

(14)

This parametrization is directly sensitive to the combination of $f_g^2 P_a$. To directly constrain $P(k)$, we must either assume a fiducial...
growth rate or marginalize over other measurements of the growth rate. For generality, we choose to treat the combination of $f_\ell^2 P_\alpha$ as a parameter.

In Macaulay et al. (2011), we used flat band powers. This parametrization was sufficient to demonstrate the large effect of including just the dipole or higher moments of the velocity field. However, in the widest, single-band parametrization, the flat bands can introduce an apparent artificial shift towards an excess of power, shown in the upper panel of Fig. 2. We find that when we factor in a fiducial CDM power spectrum into the window function, $P_{\text{id}}(k)$, and allow a constant amplitude of this power spectrum, $A_\alpha$, to vary, we obtain an amplitude which is consistent with CDM. That is, for the same average amplitude of $P(k)$, the most likely value can depend on the slope of the band within the band range. We find in practice that this shift is most significant for the single-band parametrization, and when we allow several bands to vary across the range, the slope of each band is less significant. Nevertheless, for consistency and completeness, we use CDM-shaped bands for all parametrizations, varying the average amplitude within each band. The kernel in this case is

$$K_\alpha = \int_{k_\alpha}^{k_{\alpha+1}} dk f_{\text{id}}(k) P_{\text{id}}(k),$$

so our velocity covariance matrix is now

$$R_{\alpha\beta} = \frac{(H)^2}{2}\int f_\ell^2 \sum_{\alpha} A_\alpha K_\alpha,$$

where our parameter is now $A_\alpha$, the amplitude of the fiducial power spectrum in each band. We thus expect $A_\alpha = 1$ in all bands for a CDM velocity field. To more easily compare $A_\alpha$ to expectations, we multiply the results by the mean of the power spectrum in each band, $\langle P_\alpha \rangle$, given by

$$\langle P_\alpha \rangle = \frac{\int_{k_\alpha}^{k_{\alpha+1}} dk P_{\text{id}}(k)}{k_{\alpha+1} - k_\alpha}.$$

Although this parametrization specifies the shape of the power spectrum within each band, we see in Section 4 in simulated catalogues that the method is fairly robust to the choice of fiducial power spectrum. We find that the catalogue method is sensitive to the velocity dispersion parameter and thus treat it as a free parameter in the manner of Ma et al. (2011). To directly compare between the catalogue and moments methods, we repeat much of the analysis of Macaulay et al. (2011) with $\sigma_*$ as a free parameter, although we find that the contours are fairly insensitive to the choice of $\sigma_*$. Since compressing the velocity field into moments is insensitive to small-scale effects, these contours are consistent with $\sigma_* = 0$. The 1D likelihood distributions are for a fixed $\sigma_*$ of 200 km s$^{-1}$.

We use a Metropolis–Hastings Markov chain Monte Carlo method to map out the likelihood expression in terms of the band powers and velocity dispersion. The error bars plotted on the power spectrum plots are calculated at the one standard deviation confidence level from the marginalized likelihood distribution for each band power. Where the likelihood peaks at zero this is plotted without a marker, and the error bar represents the extent of the upper bound.

### 3 PECULIAR VELOCITY DATA

We primarily study the COMPOSITE peculiar velocity catalogue, which consists of 4537 individual peculiar velocity measurements and a characteristic depth of $33 h^{-1}$ Mpc, compiled by Feldman et al. (2010). The COMPOSITE catalogue is composed of several sub-catalogues, which we also consider individually. The largest sub-catalogue is the Spiral Field I-band (SFI)++ sample, which consists of 3456 TF measurements. We analyse the field galaxies and groups in the SFI++ sample separately, as SFI++/i (2720 galaxies) and SFI+++ (736 measurements) (Masters et al. 2006; Springob et al. 2009a,b). We also study the combined DEEP catalogue, compiled by Watkins et al. (2009), which consists of 294 of the deepest peculiar velocity measurements and the Early-type
Figure 4. Histograms of the real surveys, and the Las Damas and Mark III simulated surveys, illustrating the distribution of line-of-sight peculiar velocities, $S$, uncertainty in $S$, $\sigma_S$, distance $r$, and coordinates $l$ and $b$. The COMPOSITE survey is plotted as a stacked histogram and is comprised of the SFI++$_f$ (black), SFI++$_g$ (green), ENEAR (purple), DEEP (red) and SMAC (brown) surveys.

NEARby galaxies (ENEAR) catalogue (da Costa et al. 2000). The smallest catalogue we consider individually is the SMAC catalogue (Hudson et al. 2004), which is a sub-set of the DEEP catalogue.

We test our procedures on peculiar velocity catalogues generated from $\Lambda$CDM simulations. We analyse the set of 20 simulated Mark III catalogues drawn from realizations of the Virgo simulation (Kolatt et al. 1996), consisting of 1300 entries each (some of the catalogues consisted of slightly more than 1300 entries – these were trimmed to 1300 for consistency). We also study six simulated catalogues from the Las Damas simulation (McBride et al., in preparation), designed to resemble the SFI++$_f$ catalogue with 2720 entries. Histograms of the real and simulated surveys are shown in Fig. 4.

We study the simulated data sets with both the catalogue and moments methods. We analyse the real data with the catalogue method for the combined COMPOSITE set and the five sub-catalogues. We find that the sub-catalogues are too small to reliably study the moments alone, so we present here results with the moments method only for the COMPOSITE catalogue.

4 RESULTS

4.1 Simulated data

We begin by testing our method on peculiar velocity catalogues generated from $\Lambda$CDM simulations. We start the analysis with the simplest parametrization: one band power. We choose a window function range of $k = 0.002$–$0.196$ $h^{-1}$ Mpc to match the $k$ range used in Macaulay et al. (2011). We also include the velocity dispersion as a free parameter. Results are shown in Fig. 5.

We find that for this band-power parametrization, the velocity dispersion is uncorrelated with the power spectrum amplitude. The velocity dispersion is slightly higher than the $\Lambda$CDM expectation for the Las Damas mocks, although it is lower in the Mark III mocks. In both sets of mocks, we note a small systematic shift from the $\Lambda$CDM expectation. As this shift is in opposite directions for the Mark III and Las Damas mocks, it seems reasonable to conclude that this may be due to the many particularities of generating a mock catalogue from an underlying power spectrum, as opposed to a systematic shift introduced by our method. In other words, the Mark III and Las Damas mocks taken together surround the $\Lambda$CDM expectation well. Following Macaulay et al. (2011), we next consider a parametrization with three band powers, spanning the same $k$ range with bands evenly spaced in $\log k$. The results are shown in Fig. 6.

We will refer to the bands from the largest scales to the smallest scales as bands 1 to 3. We find that the uncertainty in band 1 is larger in the simulated data with the catalogue method than the moments method (not plotted). The uncertainty in band 1 is

Figure 5. Constraints on the velocity dispersion parameter $\sigma_*$ and one band power, in the range $k = 0.002$–$0.196$ $h^{-1}$ Mpc, for simulated peculiar velocity surveys from the Las Damas and Mark III simulations. The markers represent the peak of the likelihood for each catalogue. The contours are one standard deviation uncertainty about the peak likelihood, which we have only plotted for three catalogues for each simulation set to prevent the plot from becoming overcrowded. Similarly, we only plot results for 10 of the Mark III catalogues. These uncertainty ranges are typical for the points plotted here.
Figure 6. Results from the Mark III and Las Damas mocks in three band powers. The velocity dispersion was varied as a free parameter and marginalized over in these results. The grey curve shows the $\Lambda$CDM power spectrum. The horizontal black lines span the $k$ ranges of the band powers and indicate the average value of the power spectrum across this range. The results should be compared directly to these. The markers are the marginalized results for each band power, and for each of the Mark III and Las Damas surveys. The $k$ location within each band is arbitrary; each point should be fully considered equally at the centre of the band, spanning the full width.

particularly important for understanding the high dipole moment and will be discussed further in Section 5. Both sets of catalogues are much more sensitive in band 3 than with the moments method; we thus decide to extend the band-power parametrization by adding two more bands (4 and 5) at smaller scales. Results are shown in Fig. 7.

We find that band 5 is anticorrelated with the velocity dispersion parameter. This is not surprising, given the $\sim 5\, h^{-1}$ Mpc scales spanned by this band. We are encouraged to see a difference at over $1\sigma$ from the non-linear HALOFIT (Smith et al. 2003) corrections to the galaxy power spectra, illustrating the ability of peculiar ve-

Figure 7. Same as Fig. 6, but with two additional bands added at smaller scales. The smallest scale band is at scales for which galaxy power spectra must be corrected for (e.g. with HALOFIT). With the peculiar velocity method, we are sensitive to the total matter distribution and can thus directly probe the linear power spectrum, without accounting for halo corrections.

Figure 8. Same as Fig. 7, but with a fiducial power spectrum corrected with HALOFIT. The black bars now represent the mean value of the HALOFIT fiducial power spectrum which was factored into the window function. The data still favour the linear power spectrum, indicating that the method is robust to the choice of fiducial power spectrum.

4.2 Real data

We now consider results from real peculiar velocity surveys. We start with the one band power and velocity dispersion parametrization, shown in Fig. 9.

Using the $\Lambda$CDM-shaped band, we find a slightly lower average amplitude than the flat band result from Macaulay et al. (2011). Although we note a small excess, the $\Lambda$CDM value is now well within the $1\sigma$ uncertainty range of the moments result. We find that the results for the velocity dispersion agree well with similar results.
from Ma et al. (2011). We find a smaller uncertainty in the band power with the catalogue method than the moments method, and a much improved constraint on the velocity dispersion parameter. We next consider a three-band parametrization, shown in Fig. 10.

With the moments method, band 3 was merely an upper limit – it is well constrained with the catalogue method. The low shear of the velocity field caused band 2 to be lower than the $\Lambda$CDM expectation. When we now analyse the full catalogue, the band agrees extremely well with the $\Lambda$CDM expectation. We still observe an excess of power in band 1, although the lower bound is not constrained here. These results are discussed further in Section 5. We next extend the parametrization with two smaller bands, as before with the simulated catalogues. The results are plotted in Fig. 11 and presented for COMPOSITE in Table 1. We find good agreement with $\Lambda$CDM in bands 3 and 4. We find that bands 1 and 2 are anticorrelated.

**Figure 10.** Same as Fig. 6 for the real peculiar velocity catalogues. As before, the $k$ position of each point within the bin is arbitrary, and each point should be fully considered at the centre of each band. The points have been ordered in each band from left to right by the number of galaxies in each catalogue. We also plot results from the moments analysis of the COMPOSITE catalogue.

**Figure 11.** Same as Fig. 7, now for real data. In band 1, we see a slight excess of power, although the uncertainty includes the $\Lambda$CDM model at the $1\sigma$ level. Band 5 favours the linear clustering power spectrum over the non-linear model.

**Table 1.** Results for the COMPOSITE five-band parametrization, as plotted in Fig. 11. Although the high dipole velocity leads to an excess of power by over a factor of 4 in band 1, the uncertainty includes the $\Lambda$CDM model within the $1\sigma$ uncertainty level.

| Band | $\Lambda$CDM | COMPOSITE |
|------|---------------|------------|
| 1    | $4.2 \times 10^3$ | $1.9\pm6.2 \times 10^4$ |
| 2    | $6.2 \times 10^1$ | $2.5\pm2.5 \times 10^3$ |
| 3    | $2.2 \times 10^1$ | $3.2\pm1.4 \times 10^3$ |
| 4    | $2.8 \times 10^2$ | $3.0\pm1.5 \times 10^2$ |
| 5    | $1.6 \times 10^1$ | $0.5\pm0.5 \times 10^1$ |

**Figure 12.** Analysing a simulated Mark III catalogue with the parametrization of Silberman et al. (2001). The results we find here agree well with the results in fig. 7 of Silberman et al. (2001).

### 4.2.1 Comparison to Silberman et al. (2001)

We also test our methodology by reproducing the results of Silberman et al. (2001), to which our method is similar. We change our bands as follows to match the bands used in their work: for $k < 0.02 h^{-1} \text{Mpc}^{-1}$, we use a $\Lambda$CDM band, which we do not vary. In the range $0.02 < k \leq 0.07$ and $0.07 < k \leq 0.2 h^{-1} \text{Mpc}^{-1}$, we use two independent flat bands of constant amplitude. For $k > 0.2 h^{-1} \text{Mpc}^{-1}$, we use a power-law band, $A_{k}k^{n}$. The spectral slope $n$ is set to $-0.95$ for the simulated Mark III catalogues and to $-1.4$ for the real SFI++/f catalogue, and the free parameter $A_{k}$ is varied. The results are shown in Fig. 12. We reproduce the slight decrement at $k \sim 0.1 h^{-1} \text{Mpc}^{-1}$ as noted by Silberman et al. (2001), which we also observe in the SFI++/f catalogue in band 3 of our five-band parametrization in Fig. 11.

### 4.3 Fitting a velocity dipole

In the three-band model, we find that the uncertainty in band 1 is larger with the catalogue method than with the moments method. We see these results in the simulated catalogues, but it is particularly important to understand the result in the COMPOSITE catalogue since it is closely related to the high velocity dipole. As can be seen in Fig. 1, the catalogue method’s window function is most similar to the window function of the shear moment and (relatively) not as sensitive to the scales probed by band 1. To try and understand these results, we use our maximum likelihood method to estimate the dipole, to compare it to the minimum variance dipole of Feldman et al. (2010). Instead of varying the power spectrum, we fix the power spectrum at the fiducial $\Lambda$CDM value and minimize parameters of the dipole, as analysed by Ma et al. (2011). We find that it is not possible to simultaneously constrain the

three-band-power spectrum and a velocity dipole. Following Ma et al. (2011), we model the dipole \( \mathbf{U} \) by subtracting the line-of-sight component of the dipole to each galaxy in the catalogue from its line-of-sight peculiar velocity, \( S_n \), to obtain a ‘tilted’ velocity, \( p_\phi \):

\[
p_\phi = S_n - \tilde{p}_n \cdot \mathbf{U}.
\]

We parametrize the dipole bulk flow as \( \mathbf{U} = (U_l, U_i, U_b) \), where \( U_l \) is the magnitude of the bulk flow (in km s\(^{-1}\)), and \( U_i \) and \( U_b \) are the directions of the flow in degrees (galactic coordinates). We also include the velocity dispersion \( \sigma \) as a free parameter, which we marginalize over to find the dipole bulk flow. We find a dipole of magnitude \( U_l = 380^{+44}_{-122} \) km s\(^{-1}\) in the direction \( U_i = 295^{+118}_{-128} \) and \( U_b = 14 \pm 18 \) degrees. The direction of the dipole is shown in Fig. 13. This is slightly slower and with a larger uncertainty than the dipole moment found by Feldman et al. (2010) of \( U_l = 416 \pm 78 \) km s\(^{-1}\) in the direction \( U_i = 282 \pm 11^\circ \) and \( U_b = 6 \pm 6 \)°, and is related to the larger uncertainty we find in band 1 with the catalogue method than the moments method. A comparison of measurements of the dipole is shown in Table 2.

Results from many different surveys and analysis methods appear to agree on the direction of the velocity dipole, at around \( l = 280^\circ \) and \( b = 10^\circ \), within an uncertainty radius of about 15°. However, there is less consensus as to the magnitude of the dipole. The magnitude of the dipole (and the corresponding uncertainty) can depend on the depth of the survey, the treatment of outliers and the weighting of galaxies. Even so, we can very conservatively state that the magnitude of the velocity dipole out to 100\(h^{-1}\) Mpc is a factor of several times higher than the \( \Lambda \)CDM expectation.

### 5 DISCUSSION AND CONCLUSIONS

In terms of understanding the high dipole moment, the main difference between the two methods we have considered here is that the catalogue method finds an excess of power in band 1 with an uncertainty which includes the \( \Lambda \)CDM model at the 1σ level, while the moments method finds an excess of power with an uncertainty which excludes the \( \Lambda \)CDM model at over the 1σ level. This is the issue we now consider. The power spectrum at these scales is closely linked to the magnitude of the dipole moment, where we similarly find a larger uncertainty with the catalogue method than the minimum variance moments result. The key to the different results is the minimum variance weights, which are designed to be sensitive to the largest scales at the expense of small-scale information. Indeed, of the sub-catalogues we analyse with the catalogue method, band 1 is best constrained by the DEEP and SMAC samples, which are the deepest of the sub-catalogues considered here. While both DEEP and SMAC are included within COMPOSITE, we find that the additional, shallower galaxies are effectively acting as noise as far as constraints on band 1 are concerned. Essentially, the minimum variance weights achieve this effect to a maximal extent: preferentially weighting the deeper galaxies with the cleanest measurement of the velocity moments at the expense of small-scale information.

On smaller scales, we also find a difference between the two methods in band 2. We find that the catalogue method agrees extremely well with the \( \Lambda \)CDM model, while the moments method underestimates the power. This is due to the low shear of the velocity field, which provides most sensitivity at the scales of band 2. When we analyse the full velocity catalogue, the small-scale motions not modelled by the moments appear to combine to provide a constraint which again agrees extremely well with \( \Lambda \)CDM. In much the same way as the one-band parametrization in Macaulay et al. (2011) illustrated the difference of including only the dipole or additionally the shear and octupole, the result in band 2 highlights the effect of considering only moments of the velocity field, or the full information available to us.

In the parametrization we have chosen, we have imposed that \( P(k) = 0 \) outside the range of the band powers, which could, in principle, affect the results in the bands at the edge of the parametrization. However, for the five-band parametrization, the range of the bands is sufficiently wide that the entire sensitivity range of the catalogues is covered, and the bands are insensitive to power beyond

### Table 2. Comparison of dipole measurements within 100\(h^{-1}\) Mpc. This work, Watkins et al. (2009), Feldman et al. (2010) and Ma et al. (2011) all study the COMPOSITE catalogue, whereas Nusser & Davis (2011) study the SFI++ catalogue, which comprises the majority of COMPOSITE. The direction of the flow from different works agrees well, although there is considerable variation in the magnitude of the flow. The magnitude of the flow can depend strongly on the depth of the survey, how galaxies at different depths are weighted and the sensitivity of the method for the fiducial power spectrum.

|       | \( U_l \) (km s\(^{-1}\)) | \( U_i \) (°) | \( U_b \) (°) |
|-------|----------------|-------------|-------------|
| Watkins et al. (2009) | 407 ± 81 | 287 ± 9 | 8 ± 6 |
| Feldman et al. (2010) | 416 ± 78 | 282 ± 11 | 6 ± 6 |
| Ma et al. (2011) | 340 ± 130 | 285.1 ± 23.9 | 9.1 ± 18.5 |
| Nusser & Davis (2011) (SFI++, 40\(h^{-1}\) Mpc) | 333 ± 38 | 276 ± 3 | 14 ± 3 |
| (SFI++, 100\(h^{-1}\) Mpc) | 257 ± 44 | 279 ± 6 | 10 ± 6 |
| This work | 380 ± 99 | 295 ± 18 | 14 ± 18 |

these scales. We can also directly assess this effect by comparing the three- and five-band models we have presented here. In the three-band model, we have $P(k) = 0$ at the scales where $P(k) \neq 0$ in the five-band model (when we include bands 4 and 5). However, we find that the results in band 3 are similar for both models (as can be seen in Figs 6 and 7 for the simulated catalogues and Figs 10 and 11 for the real catalogues) whether the neighbouring band is zero (the three-band model) or non-zero (the five-band model).

We can also consider the issue of whether our method is robust to systematic errors in the peculiar velocity data. For example, the TF and FP measurements we consider both depend on the assumed mass-to-light ratio of the observed galaxies. To quantify the effect of systematic errors in the distance indicators, we have re-analysed a simulated Mark III catalogue and the genuine SGI catalogue, where we have artificially introduced a systematic offset in the distance indicator and then repeated the power spectrum analysis. This mimics a systematic error which may be introduced by incorrectly determining the intrinsic luminosity of the galaxies. We have analysed each catalogue with eight different artificial offsets in the distance indicators in the range from an underestimate of the distance by a factor of 0.6 (corresponding to an overestimate of the peculiar velocity) to an overestimate of the distance uncertainty by a factor of 1.4 (corresponding to an underestimate of the peculiar velocity). As expected, we find a consistent overestimate of the band powers when the peculiar velocity is overestimated and a consistent underestimate in the band powers when the peculiar velocity is underestimated. We find that the ultimate systematic error in the bands scales linearly as approximately twice the error of the artificial distance offset.

However, a robust indication that such systematic errors in the distance measurements are not problematic is that we observe similar results in each of the sub-catalogues of COMPOSITE that we study. The DEEP and SFI++ catalogues consist of different distance indicators, and we observe similar results for both the power spectrum fitting and dipole fitting: there is no individual catalogue which is anomalous.

Perhaps more problematic may be systematic errors which can introduce a dipole variation in the observed luminosities, such as galactic extinction. Such a systematic effect would affect all the catalogues in the same manner and could also mimic a bulk flow. From analysing moments of the velocity field, we know that a velocity dipole has most effect on the large scales of bands 1 and 2; the results we find in bands 3, 4 and 5 should be fairly robust to any systematic errors which introduce a dipole variation. As for bands 1 and 2, although some of the velocity dipole could, in principle, be due to galactic extinction, it would then be difficult to reconcile with the low shear of the velocity field, and even harder to mimic with systematic effects. In other words, the high dipole and low shear, when considered together, are indicative of the large-scale overdensities we see in band 1 and are difficult to fully mimic with systematic effects.

To conclude, we find that inferring the underlying power spectrum from peculiar velocity catalogues continues the general trend of Macaulay et al. (2011) that including more details in the velocity field improves the agreement with the $\Lambda$CDM model. Specifically, we observe good agreement with $\Lambda$CDM on scales of $k > 0.01\ h\ Mpc^{-1}$, although the agreement with $\Lambda$CDM in band 1 from the catalogue method is only due to the larger uncertainty than from the moments method. While the high dipole moment alone may appear anomalous, when we consider the full peculiar velocity measurements, we find a power spectrum which agrees well with the $\Lambda$CDM model.
