Prevalence, Knowledge and Treatment of Systemic Arterial Hypertension in A Campaign Day

Elizabeth Do Espírito Santo Cestário, Anderson Aparecido Santim, Beatriz Beretta Alves, Beatriz Pereira Alcarde, Beatriz Sanches Rodrigues, Catarina de Souza Nascimento, Fernanda de Almeida Spósito, Lauane Carolina Maciel Fernandes, Leticia Fernandes Garcia, Roberta Bonamim Fiorilli, Vinicius Cardoso de Leão, Vinicius Cavallari

ABSTRACT

Hypertension affects 1.4 billion of the world population, being considered the main cause of cardiovascular diseases and, therefore, an important cause of premature and preventable mortality worldwide. It is associated with complications such as atherosclerotic coronary artery disease, congestive heart failure, stroke, intracerebral hemorrhage, and chronic kidney disease. Given this prevalence and risk, strategies were created to control the disease, such as changes in lifestyle and use of medications. However, non-adherence to treatment is a frequent concern and it is associated with adverse results and an increased number of complications. Therefore, the present study aims to present the incidence of arterial hypertension in the population of a city in the inland part of São Paulo, relating it to its risk factors, adherence to treatment and disease control. The objective is evaluating the incidence and rate of uncontrolled systemic arterial hypertension on a campaign day in a city in the inland part of São Paulo. The method is observational, cross-sectional, descriptive, population-based study, random sample of 545 individuals, 231 women and 314 men, collected in a city in the northwest of São Paulo on a campaign day. The study showed a prevalence of 46.24% for hypertensive patients, with 88.9% adherence to treatment and pressure loss of 34.23%. Among the analyzed hypertensive patients, there was a higher incidence among the elderly, obese, and people with diabetes mellitus. Regarding adherence and disease control, better results were noted among patients with complications such as AMI and thrombotic events, and less adherence among obese, alcoholics and smokers. The results of the present study are consistent with literature data, showing that even with knowledge of the disease, part of the population does not have adequate treatment, showing the need for integrated health policies for early diagnosis, distribution and treatment regulation, and actions to improve lifestyle.

Keywords: Cardiovascular disease, hypertension, uncontrolled hypertension.

I. INTRODUCTION

The increase in blood pressure is defined, according to the American College of Cardiology (ACC) and the American Heart Association (AHA), as Blood Pressure (BP) ≥130/80 mm Hg. Currently, it affects 1.4 billion people of the world population, being considered the main cause of cardiovascular diseases and, therefore, an important cause of premature and preventable mortality worldwide. Among its risk factors are genetic and behavioral factors, such as age, race, family history, obesity, diet, physical inactivity and consumption of tobacco and alcohol [1]-[3]. In relation to complications, the increase in blood pressure can lead to atherosclerotic coronary artery disease, heart failure (HF),
stroke, intracerebral hemorrhage and chronic kidney disease (CKD). It represents an association with 47% of all ischemic heart disease events and 54% of all strokes in the world [1].

Given this prevalence and risk, strategies were created to control the disease, such as changes in lifestyle and use of medications. However, non-adherence to treatment is a frequent concern and it is associated with adverse results and an increased number of complications. To date, there has been no systematic review or meta-analysis carried out to quantify and justify non-adherence, which hampers interventions and strategies to improve this reality [4]-[6].

Among the forms of control, several studies have demonstrated lifestyle modification approaches to reduce or prevent hypertension. Reducing body weight, performing regular physical activities, reducing salt or sodium intake, increasing potassium supplementation and avoiding harmful alcohol use are recommended. Regarding healthy eating, the Dietary Approaches to Stop Hypertension (DASH) argues that it can result in increased intake of potassium, magnesium, calcium and fibers, and research shows that it can reduce blood pressure, improve the lipid profile, contribute to glycemic control and reduce cardiovascular risk [7], [8].

As for the change in lifestyle, governments were encouraged to invest in population strategies and promote their individual management. In this context, current guidelines recommend physical activity and regular exercise as part of first-line therapy in primary and secondary prevention of hypertension [9].

Among antihypertensive agents, it has been observed that initial low-dose treatment with two or three antihypertensive agents is more effective than the standard dose of monotherapy. However, the number of pills can have an influence on medical adherence. Recent data indicate that an increase in the number of antihypertensive drugs would lead to loss of clinical adherence by up to 80%, increasing the risk of complications [10].

As chronic diseases are responsible for a large number of hospitalizations and mortality, their prevention is the best way to improve the population's quality of life and public spending, after all, more than 1 billion adults lived with hypertension in 2015, and the majority in low- and middle-income countries [11].

II. OBJECTIVES

To evaluate the lack of control of Systemic Arterial Hypertension during a campaign day in a city in the inland part of São Paulo. For this, the prevalence of hypertensive patients was evaluated, as well as the presence of risk factors and associated complications. In addition, the adherence to drug treatment in hypertensive patients who participated on the day of the campaign and the lack of knowledge about the diagnosis of SAH on the day of the campaign.

III. CASUISTIC AND METHODS

Observational, cross-sectional, descriptive, population-based study, random sample collected in a city in the northwest of São Paulo on a campaign day.

The sample comprised 545 individuals, 231 women and 314 men randomly selected from individuals who passed downtown and who agreed to participate in the project. After clarifying that the data collected would be anonymous, they authorized their data to be later used for academic purposes.

The instrument used was a data collection form sent by the International Hypertension Society, which contained the variables: sex, age, height, weight, ethnicity, BP measurement in the last 12 months, previous diagnosis of SAH and diabetes mellitus, continuous use of antihypertensive medications, smoking, alcohol consumption, history of acute myocardial infarction (AMI) or previous thrombosis. Regarding the measurements, weight and height were evaluated using a digital scale. BP measurement with a manual BIC sphygmomanometer on the left arm with three BP measurements and counting of three heart rates, both at 1-minute intervals each.

SAH was considered as systolic BP ≥140 mm Hg and/or diastolic BP ≥90 mm Hg (considering the average of 3 measurements, with an interval of 1 minute each) and/or positive answer to the question “Are you currently taking medication to decrease your BP?”. Hypertension awareness was determined by hypertensive patients who answered affirmatively to the question: “Have you ever been told by a doctor or other health professional that you had hypertension, also called high blood pressure?” The treatment of hypertension was established by the participants who answered “yes” to the question: “Due to your hypertension/high blood pressure, are you taking prescription drugs?”.

The event was organized by the Academic League of Cardiology of Medicine of Votuporanga. Data collection was performed by students from different courses in the health field, such as medicine, biomedicine, nursing, and nutrition, who had knowledge about BP measurement.

IV. RESULTS

The mean values of systolic blood pressure (SBP) and diastolic pressure (DBP) were 124.96 and 79.85 mmHg, respectively.

Considering only the 252 participants diagnosed with Systemic Arterial Hypertension (SAH), 109 (43.25%) were women and 143 (56.75%) men. SBP and DBP, respectively, were 125.92 x 80.53 mmHg in males and 123.69 x 79.07 mmHg in females. The prevalence of SAH in women was higher than in men (47.19% and 45.54%, respectively). It is noted that men have slightly better adherence to treatment (88.11% x 88.07%) and a lower proportion of individuals with uncontrolled pressure (31.75% x 34.37%), but greater ignorance about being carriers of disease (47.87% x 36.06%).

The average age of the participants was 58.37 years. Hypertensive patients have a higher average age compared to those who do not have the disease (60.98 x 56.13 years, respectively). The study included 49.72% of the elderly and 50.28% of individuals under 60 years of age. When performing a comparative analysis between the two groups, it is noted that in the elderly there is a higher prevalence of SAH (52.04% x 40.44%) and greater ignorance about being comorbid (44.00% x 42.50%), however, they adhere better to the treatment (95.71% x 78.18%), and have a lower rate of uncontrolled pressure values (29.85% x 38.37%).

DOI: http://dx.doi.org/10.24018/ejmed.2022.4.1.1126
The study had 180 (33.03%) self-declared drinkers, whose prevalence of hypertension was 45.55%. When comparing them to non-drinkers, there is less adherence to the treatment of SAH (82.93% drinkers x 90.59% non-drinkers) and greater uncontrolled blood pressure levels (33.82% drinkers x 32.47% non-drinkers). However, the group of non-alcoholics has a higher proportion of individuals without a diagnosis of SAH and with high blood pressure on the day of the event (47.54% x 71.27%), indicating greater ignorance about the pathology.

Among the 545 participants, 69 (12.66%) claimed to be smokers. The rate of hypertensive patients in this group corresponded to 31.88%. When analyzing the group of smokers and non-smokers and comparing them, respectively, it was concluded that smokers have less adherence to the use of antihypertensive drugs (68.18% x 90.00%), greater uncontrolled blood pressure (40.00% x 32.37%) and greater ignorance about having SAH (67.85% x 37.79%).

From all the individuals, 79 (14.49%) were diabetic. The prevalence of SAH in this group was 69.62%. Performing a comparative analysis between diabetics and non-diabetics, respectively, it is observed that diabetics have better adherence to treatment (94.54% x 86.29%), less uncontrolled pressure values (26.92% x 34.71 %) and lower proportion of individuals without previous diagnosis of SAH with high blood pressure values on the day of the event (33.33% x 45.04%).

In total, 160 (29.68%) participants were obese. Of these, 53.75% were hypertensive. It is noted that the prevalence of SAH increases as the BMI increases, as well (40.25% in healthy individuals; 45.37% in overweight; 50.83% in class 1 obesity).
obesity; 60.53% in class 2 obesity and 100% in class 3 obesity). When correlating them with the non-obese, it is observed that the obese adhere less to the treatment (84.88% x 89.44%), have greater pressure loss (35.62% x 31.94%), however they have less proportion of individuals with high blood pressure levels without previous diagnosis of SAH (41.67% x 44.68%)

One of the possible complications for patients with SAH is Acute Myocardial Infarction (AMI). Of the 545 people, 31 (5.69%) had a history of AMI. The prevalence of SAH in these individuals was 67.74%. When comparing the participants with and without previous ischemic cardiac events, respectively, it is noted that those who already had a heart attack have greater adherence to the treatment of SAH (95.24% x 87.45%), less uncontrolled pressure values (25.00 % x 33.66%) and a smaller proportion of people who were not diagnosed with SAH but had high BP on the day of the event (33.33% x 44.44%).

Another common complication in hypertensive patients is thrombotic events. The study obtained 8 (1.47%) people with a previous history of thrombosis. The prevalence of hypertension in this group was 62.50%. When analyzing individuals with and without a thrombotic history and comparing them, respectively, it was concluded that those who had a previous thrombosis episode adhere better to the treatment (100.00% x 87.85%), have less uncontrolled blood pressure values (20.00% x 33.18%) and better knowledge about having SAH, since all members of this group with high blood pressure had a previous diagnosis, while 43.51% of the group without a history of thrombosis had high BP without being previously diagnosed as hypertensive.

The overall prevalence of hypertension in the study was 46.24%, with a rate of adherence to treatment of 88.09% and uncontrolled pressure levels in 34.23% of hypertensive patients. In addition, 43.23% of individuals with high BP at the event were not diagnosed with SAH and 7.74% were diagnosed, but they were not using antihypertensive medications.

In comparisons between hypertensive and non-hypertensive individuals, respectively, with the variables present in the study, it is noted that hypertensive individuals are older (60.98 years x 56.13 years), have greater weight (77.77 kg x 74.90 kg), shorter height (148.85 cm x 152.09 cm), higher SBP and DBP (127.70 and 81.50 mmHg x 122.61 and 78.43 mmHg), greater relationship with obesity (34.68 % x 25.52%) and diabetes Melitus (21.83% x 8.19%), lower prevalence of alcoholism (32.41% x 33.45%) and smoking (8.73% x 16.04%), and a higher occurrence of complications such as AMI (8.33% x 3.41%) and thrombotic events (1.98% x 1.02%).

### TABLE I: BLOOD PRESSURE GENERAL MEAN

| General | Mean | Standard Deviation | Confidence Interval (95%) |
|---------|------|--------------------|--------------------------|
| Age     | 58,370 | 13,695            | (57,216-59,524)          |
| HR      | 72,630 | 11,149            | (71,694-73,566)          |
| SBP     | 124,964 | 15,422           | (123,669-126,259)        |
| DBP     | 79,857 | 11,051            | (78,929-80,785)          |
| MBP     | 94,893 | 11,500            | (93,928-95,858)          |
| PP      | 45,107 | 11,313            | (44,157-46,057)          |
| BMI     | 27,653 | 4.489             | (27,273-28,033)          |
V. DISCUSSION

According to the World Health Organization (WHO), the number of individuals with SAH has increased significantly in the last 40 years, with an estimated 1.5 billion hypertensive individuals for the year 2025. Globally, Africa is the country with the highest index of SAH, with 27% of the hypertensive population, followed by the regions of the Eastern Mediterranean, Southeast Asia (25%) and Europe (23%). The lowest incidences were found in the Americas (18%) and the Western Pacific region (19%) [12], [13].

In Brazil, the disease is estimated at 36 million adult individuals, contributing directly or indirectly to 50% of deaths from cardiovascular disease. Associated with diabetes mellitus (DM) and its cardiac, renal and vascular complications, it has a high impact on the loss of work productivity and family income, estimated at US $ 4.18 billion between 2006 and 2015. However, it is important to note that, in Brazil, the prevalence of arterial hypertension varies according to the population studied and the evaluation method [14], [15].

AHA updates in 2019 point to an estimated 116.4 million (46%) adults in the U.S. with hypertension [16]. The overall prevalence of hypertension in the study was 46.24%, similar to the result corroborated above, with a rate of adherence to treatment of 88.09% and uncontrolled pressure levels in 34.23% of hypertensive patients. In addition, 43.23% of individuals with high BP at the event were not diagnosed with SAH.

The control of blood pressure within the target plays a critical role in reducing associated CVD; however, in analysis, the rate of uncontrolled blood pressure levels in this study was 34.23% for hypertensive patients.

Diverging from the results obtained, the metaanalysis of Amare et al. in Ethiopia found a prevalence of uncontrolled hypertension among hypertensive patients undergoing treatment of 48% [2].

Similar values related to the lack of control of SAH have been found in several populations. Populations from 90 countries worldwide showed a rate of 62.9%, low- and middle-income countries showed a lack of control of 73.7%: with emphasis on rural India (89.7%), urban India (79.8%) and China (91.9%). In another meta-analysis in Brazil, there was a lack of control of 68.2% in men and 43.1% in women, all highly above the current study [2].

However, inferior results of uncontrolled hypertension were found in Dutch (30%), English (23.9%), Canadian (14%) and American (21.2%) studies [2]. Thus, the high prevalence of uncontrolled hypertension observed in this study may be associated with socioeconomic factors, low educational level and poverty.

A 2017 study from Spain showed that one in three adults is hypertensive, with only half of those undergoing treatment adequately controlling the disease, resulting in 40,000 cardiovascular deaths annually attributable to the disease. 17

In an American study, the prevalence of hypertension according to National Health and Nutrition Surveys (NHANES) of the US population aged ≥18 years in 2008, there are approximately 67.5 million hypertensive adults in the United States, with more than 33 million people with uncontrolled SAH. However, the proportion of hypertensive patients with uncontrolled blood pressure decreased from 73.2% in 1988 to 1994 to 52.5% in 2005 to 2008 [18].

In reference to a Russian study among hypertensive patients, regardless of treatment, blood pressure control was achieved in 22% of men while in women it was 33% [19].

Individuals in Russia were more likely to lose control of hypertension, with 55.7% in men and 42.7% in women compared to Norway, where the corresponding percentages were 43.6% and 33.0%. 36 In the present study, the rates of uncontrolled hypertension in women and men were 34.37% and 31.75%, respectively, with differences in relation to uncontrolled and sex rates [19].

Ultimately, this study showed a SAH control rate of approximately 70% in the elderly population. Another Brazilian study showed results that differed from this one, in which only half (50.7%) of the elderly Brazilian hypertensive population undergoing drug treatment had controlled blood pressure levels. Comparatively, the prevalence of controlled hypertension in the study was 46.24%, similar...
blood pressure levels among elderly hypertensive patients, who used medication, was higher than that observed in Canada (66%), the United States (48%) and in populations in developing countries (between 20 and 36%) [20].

On average, the controlled percentage of SAH in the Arab countries is comparable to the 8% and 23% reported for the USA and European countries, respectively [21].

According to the National Health and Nutrition Surveys (NHANES) of the US population aged ≥18 years in 2008 of the 33 million people with uncontrolled SAH, approximately 13 million of the uncontrolled hypertensive patients were unaware of the disease and only 20 million are aware of their hypertension [18].

With regard to awareness of hypertension, our findings of 43.23% of individuals with high BP at the event did not have the diagnosis of SAH corroborate those of economically developed countries, in which approximately half to two thirds of hypertensive patients were aware of their diagnosis. Limited access to health services, especially in rural areas, and the lack of preventive care coupled with the silent symptoms of SAH, may contribute to the lack of knowledge and the inadequate rate of control in the Arab population [21].

A study in an urban Indian population over 25 years old estimated rates of awareness, treatment and control of SAH of 42.0%, 37.6% and 20.2% for urban India and 25.3%, 25.1% and 10.7% for rural India. Similar urban-rural differences have been reported in other low-income countries [22].

The prevalence of hypertension is lowest in Canada (19.5%) and highest in the USA (29%) and England (30%). Awareness of hypertension is close to 80% in the USA (81%), Canada (83%) and lower in England (65%). England also has lower levels of treatment for hypertension (England 51%; USA 74%; Canada 80%) and control (England 27%; USA 53%; Canada 66%). Among individuals treated for hypertension, the controlled proportion is lower in England (53%), compared to 71% in the USA and 82% in Canada. 23

According to Van Rossum et al., several studies have shown that a considerable proportion of hypertensive patients are not aware of having a diagnosis of SAH and that, among those who are aware, a considerable proportion is not treated. However, awareness frequencies appear to vary substantially from 23% in China to 97% in women in the United States.

VI. CONCLUSION

The results are consistent with literature data showing that even though they are aware of the disease, some patients are not adequately treated, since the prevalence of uncontrolled hypertension in this study was high. This is alarming, due to the increased risk of cardiovascular complications. Reality that imposes additional burdens on the country's health system, highlighting the need for public health policies in order to implement strategic interventions focused on achieving an ideal blood pressure among treated hypertensive patients.

Given these data, the challenge continues: to develop, in practice, measures that can improve BP control, the adherence of patients with SAH to treatment, as well as reducing the factors that influence their adherence.

Determining the prevalence of uncontrolled SAH will help understand the magnitude of the problem and develop strategies to reduce the imposed burden of CVD.

To combat these potentially adverse trends and improve the overall control of hypertension, integrated health policies are needed, from actions that guarantee the improvement of lifestyle with healthy habits, early diagnosis to public policies to guarantee the purchase, distribution and regular use of effective antihypertensive drugs.
