Abstract

In this paper, we consider the problem of minimizing a linear functional subject to uncertain linear and bilinear matrix inequalities, which depend in a possibly nonlinear way on a vector of uncertain parameters. Motivated by recent results in statistical learning theory, we show that probabilistic guaranteed solutions can be obtained by means of randomized algorithms. In particular, we show that the Vapnik-Chervonenkis dimension (VC-dimension) of the two problems is finite, and we compute upper bounds on it. In turn, these bounds allow us to derive explicitly the sample complexity of these problems. Using these bounds, in the second part of the paper, we derive a sequential scheme, based on a sequence of optimization and validation steps. The algorithm is on the same lines of recent schemes proposed for similar problems, but improves both in terms of complexity and generality. The effectiveness of this approach is shown using a linear model of a robot manipulator subject to uncertain parameters.

Key words: Statistical Learning Theory; Vapnik-Chervonenkis Dimension; Uncertain Linear/Bilinear Matrix Inequality; Randomized Algorithms; Probabilistic Design.

1 Introduction

Statistical learning theory is a very effective tool in dealing with various applications, which include neural networks and control systems, see for instance Vidyasagar (2002). The main objective of this theory is to extend convergence properties of the empirical mean, which can be computed with a Monte Carlo simulation, from finite families to infinite families of functions. For finite families, these properties can be easily established by means of a repeated application of the so-called Hoeffding inequality, and are related to the well-known law of large numbers, see for instance Tempo et al. (2013). On the other hand, for infinite families much deeper technical tools are needed and have been developed in the seminal work of Vapnik & Chervonenkis (1971). In this case, the main issue is to establish uniform convergence of empirical means. In particular, this requires to establish whether or not a combinatorial parameter called the Vapnik-Chervonenkis dimension (VC-dimension) is finite, see Vapnik (1998).

Subsequent contributions on statistical learning theory by Vidyasagar (2001) followed two main research directions: First, to demonstrate that this theory is indeed an effective tool for control of systems affected by uncertainty. Second, to “invert” the bounds provided by Vapnik and Chervonenkis, introducing the concept of sample complexity. Roughly speaking, when dealing with control of uncertain systems, the sample complexity provides the number of random samples of the uncertainty that should be drawn to derive a stabilizing controller (or a controller which attains a given $H_\infty$-norm bound on the closed-loop sensitivity function), with sufficiently high probabilistic accuracy and confidence. Since the sample complexity is a function of the accuracy, confidence and the VC-dimension, specific bounds on this combinatorial parameter should be derived. In turn, this involves a problem reformulation in terms of Boolean functions, and the evaluation of the number of required polynomial inequalities, their order and the number of design variables.

For various stabilization problems, which include stability of interval matrices and simultaneous stabilization with static output feedback, bounds on the VC-dimension have been derived in Vidyasagar & Blondel (2001). In this paper, we continue this specific line of research, and we compute the VC-dimension for control problems formulated in terms of uncertain linear matrix inequalities (LMIs) and bilinear matrix inequalities (BMIs). It is well-known that many robust and optimal control problems can be indeed formulated in these forms, see for instance Boyd et al. (1994); Goh et al. (1995); Kanev et al. (2004); VanAntwerp & Braatz (2000). However, due to the presence of uncertainty it is often unclear how uncertain LMIs and BMIs can be effectively solved, for example when the uncertainty enters nonlinearly into the control system. In these cases, relaxation techniques are usually introduced, leading to conservative results.

In the present paper, we provide new bounds for the VC-dimension for uncertain LMIs and BMIs. These bounds are then combined with recent results in Alamo et al. (2009) to establish the sample complexity of uncertain LMIs and BMIs. We remark that the sample complexity is independent from the number of uncertain parameters entering
into the LMIs and BMIs, and on their functional relationship. Hence, the related randomized algorithms run in polynomial-time. However, for relatively small values of the probabilistic accuracy and confidence, the sample complexity turns out to be very large, as usual in the context of statistical learning theory. For this reason, randomized algorithms based on a direct application of these bounds may be of limited use in practice. To alleviate this difficulty, in the second part of the paper we propose a sequential algorithm specifically tailored to the problem at hand. This algorithm has some similarities with other sequential algorithms previously developed for other problems in the area of randomized algorithms for control of uncertain systems, see Calafiore et al. (2011), and in particular Alamo et al. (2012, 2009); Chamanbaz et al. (2013b); Koltchinskii et al. (2000).

Finally, the effectiveness of this approach is shown by a numerical example related to the static output feedback stabilization of an uncertain robot manipulator joint. In particular, the objective is to design a static output feedback controller which minimizes the worst-case $H_{\infty}$ norm. The numerical performance of the proposed sequential algorithm is evaluated and compared with the theoretical sample-complexity previously derived.

2 Problem Formulation

Most robust and optimal control problems can be formulated as linear or bilinear matrix inequality (LMI or BMI). In the case where problem data involves uncertain parameters the LMI and BMI problems are in the form of semi-infinite optimization programs, due to the infinite number of constraints involved. We now formally state the uncertain LMI and BMI problems.

**Problem 1 (Uncertain Strict LMI Optimization)** Find the optimal value of $x$, if it exists, which solves the optimization problem

$$\begin{align*}
\text{minimize} & \quad c_x^T x \\
\text{subject to} & \quad F_{\text{LMI}}(x, q) = F_0(q) + \sum_{i=1}^{m_x} x_i F_i(q) \succ 0, \forall q \in \mathbb{Q}
\end{align*}$$

where $x \in \mathbb{R}^{m_x}$ is the vector of optimization variables, $q \in \mathbb{Q} \subset \mathbb{R}^\ell$ is the vector of uncertain parameters bounded in the set $\mathbb{Q}$ and $F_i = F_i^T \in \mathbb{R}^{n \times n}$, $i = 0, \ldots, m_x$. The inequality $F_{\text{LMI}}(x, q) \succ 0$ means that $F_{\text{LMI}}(x, q)$ is positive definite.

**Problem 2 (Uncertain Strict BMI Optimization)** Find the optimal values of $x$ and $y$, if they exist, which solve the optimization problem

$$\begin{align*}
\text{minimize} & \quad c_x^T x + c_y^T y \\
\text{subject to} & \quad F_{\text{BMI}}(x, y, q) = F_0(q) + \sum_{i=1}^{m_x} x_i F_i(q) + \sum_{j=1}^{m_y} y_j G_j(q) + \sum_{i=1}^{m_x} \sum_{j=1}^{m_y} x_i y_j H_{ij}(q) \succ 0, \forall q \in \mathbb{Q}
\end{align*}$$
where \( x \in \mathbb{R}^{m_x} \) and \( y \in \mathbb{R}^{m_y} \) are the vectors of optimization variables, \( q \in \mathbb{Q} \subset \mathbb{R}^f \) is the vector of uncertain parameters, \( F_0 = F_0^T \in \mathbb{R}^{n \times n} \), and \( F_i = F_i^T \in \mathbb{R}^{n \times n} \), \( G_j = G_j^T \in \mathbb{R}^{n \times n} \), \( H_{ij} = H_{ij}^T \in \mathbb{R}^{n \times n} \), \( i = 1, \ldots, m_x \), \( j = 1, \ldots, m_y \).

In the present paper, we study a probabilistic framework for solving Problems 1 and 2 in which the uncertain parameters are assumed to be random variables. Furthermore, the constraints in (1) and (2) are allowed to be violated for some \( q \in \mathbb{Q} \), provided that this violation is sufficiently small. This concept is formally expressed using the notion of “probability of violation”.

**Definition 1 (Probability of Violation)** The probability of violation of \( \theta \) for the binary-valued function \( g : \mathbb{R}^{m_\theta} \times \mathbb{Q} \rightarrow \{0, 1\} \) is defined as

\[
V_g(\theta) = \Pr \{ q \in \mathbb{Q} : g(\theta, q) = 1 \} \tag{3}
\]

where \( \theta = x \in \mathbb{R}^{m_\theta} \), with \( m_\theta = m_x \), and

\[
g(\theta, q) = \begin{cases} 
0 & \text{if } F_{LMI}(\theta, q) \succ 0 \\
1 & \text{otherwise} 
\end{cases} \tag{4}
\]

for Problem 1. Similarly, \( \theta = \begin{bmatrix} x \\ y \end{bmatrix} \in \mathbb{R}^{m_\theta} \), with \( m_\theta = m_x + m_y \), and

\[
g(\theta, q) = \begin{cases} 
0 & \text{if } F_{BMI}(\theta, q) \succ 0 \\
1 & \text{otherwise} 
\end{cases} \tag{5}
\]

for Problem 2.

The probability (3) is in general very difficult to evaluate due to the difficulty of computing the multiple integrals associated with the probability of violation. Nevertheless, we can “estimate” this probability using randomization. To this end, we assume that a probability measure is given over the set \( \mathbb{Q} \), and extract \( N \) independent and identically distributed (i.i.d) samples from the set \( \mathbb{Q}^N = \mathbb{Q} \times \mathbb{Q} \times \cdots \times \mathbb{Q} \) (\( N \) times). Next, a Monte Carlo approach is employed to obtain the so called “empirical violation”.

**Definition 2 (Empirical Violation)** For given \( \theta \in \mathbb{R}^{m_\theta} \) the empirical violation of \( g(\theta, q) \) with respect to the multisample \( q = \{q^{(1)}, \ldots, q^{(N)}\} \in \mathbb{Q}^N \), based on the given density function, where \( \mathbb{Q}^N = \mathbb{Q} \times \mathbb{Q} \times \cdots \times \mathbb{Q} \) (\( N \) times). Next, a Monte Carlo approach is employed to obtain the so called “empirical violation”.

\[
\hat{V}_g(\theta, q) = \frac{1}{N} \sum_{i=1}^{N} g(\theta, q^{(i)}). \tag{6}
\]
Algorithm 1 A Randomized Strategy for Uncertain LMIs/BMIs

• Given the underlying probability density function (pdf) over the uncertainty set $Q$ and the level parameter $\rho \in [0, 1)$, extract $N$ independent identically distributed samples from $Q$ based on the underlying pdf

$$q = \{q^{(1)}, \ldots, q^{(N)}\}.$$  

• Find the optimal value, if it exists, of the following optimization problem

$$\begin{align*}
\text{minimize} & \quad c^T \theta \\
\text{subject to} & \quad \hat{V}_g(\theta, q) \leq \rho
\end{align*}$$

where $c = c_x \in \mathbb{R}^{m_x}$ for Problem 1 and $c = \begin{bmatrix} c_x \\ c_y \end{bmatrix} \in \mathbb{R}^{m_x + m_y}$ for Problem 2.

2.1 Randomized Strategy to Optimization Problems

There are a number of randomized methodologies in the literature which are based on randomization in the uncertainty space, design parameter space or both. For example, in Vidyasagar (2001) randomization in both uncertainty and design parameter spaces is employed for minimizing the empirical mean. Similarly, a bootstrap learning method and a min-max approach are presented in Koltchinskii et al. (2000) and Fujisaki & Kozawa (2006), respectively, but these papers deal with finite families. In Alamo et al. (2009) the authors proposed a randomized algorithm for infinite families which is applicable to convex and non-convex problems. Finally, a non-sequential randomized methodology for uncertain convex problems is introduced in Calafiore & Campi (2004, 2006); Campi & Garatti (2008). In Algorithm 1 we present a non-sequential randomized strategy for solving Problems 1 and 2. We remark that introducing the level parameter $\rho > 0$ enables us to handle probabilistic (soft) constraints, in the same spirit of Alamo et al. (2009). The main objective of the present paper is to derive the explicit sample complexity bound on $N$ based on statistical learning theory results.

3 Vapnik-Chervonenkis Theory

In this section, we give a very brief overview of the Vapnik-Chervonenkis theory. The material presented is classical, but a summary is instrumental to our next developments. In particular, we review some bounding inequalities which are used in the subsequent sections to derive the explicit sample bounds for solving Problems 1 and 2.

**Definition 3 (Probability of Two-sided Failure)** Given $N, \varepsilon \in (0, 1)$ and $g: \mathbb{R}^{m_x} \times Q \to \{0, 1\}$, the probability of two-sided failure denoted by $q_g(N, \varepsilon)$ is defined as

$$q_g(N, \varepsilon) = \Pr \left\{ q \in Q^N : \sup_{\theta \in \mathbb{R}^{m_y}} |V_g(\theta) - \hat{V}_g(\theta, q)| > \varepsilon \right\}.$$
The probability of two-sided failure determines how close the empirical violation is to the true probability of violation. In other words, if we extract a multisample \( q \) with cardinality \( N \) from the uncertainty set \( Q \), we guarantee that the empirical violation (6) is within \( \varepsilon \) of the true probability of violation (3) for all \( q \in Q \) except for a subset having probability measure at most \( q_g(N, \varepsilon) \). The parameter \( \varepsilon \in (0, 1) \) is called accuracy.

Let \( G \) denote the family of functions \( \{g(\theta, q) : \theta \in \mathbb{R}^{m_\theta} \} \) where \( g : \mathbb{R}^{m_\theta} \times Q \rightarrow \{0, 1\} \) is defined in (4) or in (5). The family \( G \) is said to satisfy the property of uniform convergence of empirical mean (UCEM) if \( q_g(N, \varepsilon) \rightarrow 0 \) as \( N \rightarrow \infty \) for any \( \varepsilon \in (0, 1) \). We remark that if \( G \) includes finite family of functions, it indeed has the UCEM property. However, infinite families do not necessarily enjoy the UCEM property, see Vidyasagar (2002) for several examples of this type. The formulated problems in the present paper (Problems 1 and 2) belong to the class of infinite family of functions.

We define the family \( S_g \) containing all possible sets \( S_g = \{q \in Q : g(\theta, q) = 1\} \), for \( g \) varying in \( G \). Now consider a multisample \( q = \{q^{(1)}, \ldots, q^{(N)}\} \) of cardinality \( N \). For the family of functions \( G \), let

\[
N_G(q) = \text{Card}(q \cap S_g, S_g \in S_g).
\]

In words, we say that \( S_g \) “shatters” \( q \) when \( N_G \) is equal to \( 2^N \). The notion of “shatter coefficient” also known as “growth function” is now defined formally.

**Definition 4 (Shatter Coefficient)** The shatter coefficient of the family \( G \), denoted by \( S_G(N) \), is defined as

\[
S_G(N) = \max_{q \in Q^N} N_G(q).
\]

A bound on the shatter coefficient can be obtained by Sauer lemma (Sauer, 1972), which in turn requires the computation of the VC-dimension, defined next.

**Definition 5 (VC-dimension)** The VC-dimension of the family of functions \( G \) is defined as the largest integer \( d \) for which \( S_G(N) = 2^d \).

The following result establishes a bound on the probability of two-sided failure in terms of VC-dimension.

**Theorem 1** Let \( d \) denote the VC-dimension of the family of functions \( G \). Then, for any \( \varepsilon \in (0, 1) \)

\[
q_g(N, \varepsilon) \leq 4e^{2\varepsilon} \left( \frac{2eN}{d} \right)^d e^{-N\varepsilon^2}
\]

where \( e \) is the Euler number.

This result is given in Vapnik (1998, Theorem 4.4).
4 Main Results

In view of Theorem 1, we conclude that families with finite VC-dimension $d < \infty$ enjoy the UCEM property. Hence, it is important i) to show that the collection $\mathcal{G}$ of functions has finite VC-dimension and, ii) to derive upper bounds on the VC-dimension.

4.1 Computation of Vapnik-Chervonenkis Dimension

In the next theorem, which is one of the main contributions of this paper, we derive an upper bound on the VC-dimension of the uncertain LMI and BMI in Problems 1 and 2.

**Theorem 2** The VC-dimensions of uncertain LMIs and BMIs problems (1) and (2) are upper bounded by $2m_x \log(4en^2)$ and $2(m_x + m_y) \log(4en^2)$, respectively, where $\log(.)$ denotes the logarithm to the base 2.

**Proof** See Appendix A.

It is interesting to observe that the VC-dimension of both LMIs and BMIs is linear in the number of design variables. We remark that it is not possible to compute the VC-dimension for the general case of nonlinear matrix inequality (NMI). This is due to the fact that there is no optimization variable of degree larger than one in the BMI, and this is clearly not the case for NMI. In the next subsection, we derive explicit sample bounds to be used in Algorithm 1 for solving Problems 1 and 2.

4.2 Sample Complexity Bounds

In this section, we study a number of sample bounds guaranteeing that the probability of failures is bounded by a confidence parameter $\delta \in (0, 1)$. We remark that there are several results in the literature to derive sample complexity bounds. To the best of our knowledge, the least conservative is stated in Corollary 3 in [Alamo et al. (2009)]. For given $\varepsilon, \delta \in (0, 1)$, the probability of two-sided failure (8) is bounded by $\delta$ provided that at least

$$
N \geq \frac{1.2}{\varepsilon^2} \left( \ln \frac{4e^{2\varepsilon}}{\delta} + d \ln \frac{12}{\varepsilon^2} \right) \quad (10)
$$

samples are drawn, where $d < \infty$ denotes the VC-dimension of the family of functions $\mathcal{G}$, and $\ln$ is the natural logarithm. This result is exploited in the next corollary, that provides the explicit sample complexity bounds for the probability of two-sided failure.

**Corollary 1** Suppose that $\varepsilon, \delta \in (0, 1)$ are given. Then, the probability of two-sided failure is bounded by $\delta$ if at least

$$
N_{\text{LMI}} \geq \frac{1.2}{\varepsilon^2} \left( \ln \frac{4e^{2\varepsilon}}{\delta} + 2m_x \log(4en^2) \ln \frac{12}{\varepsilon^2} \right) \quad (11)
$$
and

\[ N_{\text{BMI}} \geq \frac{1.2}{\varepsilon^2} \left( \ln \frac{4e^2\varepsilon}{\delta} + 2(m_x + m_y) \ln(4en^2) \ln \frac{12}{\varepsilon^2} \right) \]  \hspace{1cm} (12)

samples are drawn for the Problems 1 and 2 respectively.

**Proof** The statement of Corollary 1 follows immediately by combining (10) and the results of Theorem 2.

A weaker notion than the probability of two-sided failure is the “probability of one-sided constrained failure” introduced in the following definition.

**Definition 6 (Probability of One-sided Constrained Failure)** Given \( N, \varepsilon \in (0, 1) \) and \( g : \mathbb{R}^m \times \mathbb{Q} \rightarrow \{0, 1\} \), the probability of one-sided constrained failure, denoted by \( p_g(N, \varepsilon, \rho) \), is defined as

\[
p_g(N, \varepsilon, \rho) = \Pr \left\{ \exists \theta \in \mathbb{R}^m : \hat{V}_g(\theta, q) \leq \rho \text{ and } V_g(\theta) - \hat{V}_g(\theta, q) > \varepsilon \right\}. \hspace{1cm} (13)
\]

Following the same lines of Corollary 1, sample complexity bounds for the probability of one-sided constrained failure are derived.

**Corollary 2** Suppose that \( \varepsilon \in (0, 1), \delta \in (0, 1) \) and \( \rho \in [0, 1) \) are given. Then, the probability of one-sided constrained failure is bounded by \( \delta \) if at least

\[
N_{\text{LMI}} \geq \frac{5(\rho + \varepsilon)}{\varepsilon^2} \left( \ln \frac{4}{\delta} + 2m_x \ln(4en^2) \ln \frac{40(\rho + \varepsilon)}{\varepsilon^2} \right) \hspace{1cm} (14)
\]

and

\[
N_{\text{BMI}} \geq \frac{5(\rho + \varepsilon)}{\varepsilon^2} \left( \ln \frac{4}{\delta} + 2(m_x + m_y) \ln(4en^2) \ln \frac{40(\rho + \varepsilon)}{\varepsilon^2} \right) \hspace{1cm} (15)
\]

samples are drawn for the Problems 1 and 2 respectively.

**Proof** These results are an immediate consequence of Theorem 7 in Alamo et al. (2009), which states that, for given \( \varepsilon, \delta \in (0, 1) \) and \( \rho \in [0, 1) \), the probability of one-sided constrained failure is bounded by \( \delta \) provided that at least

\[
N \geq \frac{5(\rho + \varepsilon)}{\varepsilon^2} \left( \ln \frac{4}{\delta} + d \ln \frac{40(\rho + \varepsilon)}{\varepsilon^2} \right) \hspace{1cm} (16)
\]

samples are drawn, where \( d < \infty \) denotes the VC-dimension of the family of functions \( G \). The statements in Corollary 2 are derived by substituting the results of Theorem 2 into (16).

Note that the sample complexity of Corollary 2 improves upon that of Corollary 1, as shown in Figure 1. In particular, it is clear that the bounds (11) and (12) increase as \( O\left(\frac{1}{\varepsilon^2} \ln \frac{1}{\varepsilon^2}\right) \), which implies that if the accuracy level \( \varepsilon \) is chosen to be very small, the sample bounds can be very large, while (14) and (15) grow as \( O\left(\frac{1}{\varepsilon} \ln \frac{1}{\varepsilon}\right) \).
Fig. 1. Sample complexity bounds for strict BMIs, for \( \delta = 1 \times 10^{-8} \), \( m_x + m_y = 13 \), and for different BMI dimensions: \( n = 10 \) (continuous line) \( n = 50 \) (dashed line) and \( n = 100 \) (dash-dotted line). The red plots show the two-sided bound (12), while the blue plots show the one-sided constrained failure bound (15) for \( \rho = 0 \).

By comparing the LMI bounds (11) and (14) with the respective BMI bounds (12) and (15), it is clear that they behave exactly in the same way, taking into account that the number of design variables is \( m_x \) for LMIs and \( m_x + m_y \) for BMIs.

5 Semidefinite Constraints

In this section, we compute upper bounds on the VC-dimension of the semidefinite versions of Problems 1 and 2 where strict inequalities (\( > 0 \)) are replaced with non-strict inequalities (\( \geq 0 \)). Throughout the paper, non-strict (semidefinite) versions of Problems 1 and 2 are called “uncertain semidefinite LMI problem” and “uncertain semidefinite BMI problem” respectively.

In the following theorem, we establish upper bounds on the VC-dimension of uncertain semidefinite LMI and BMI problems.
Theorem 3  The VC-dimensions of uncertain semidefinite LMI and BMI problems are upper bounded by $2m_x \lg(4en^2)$ and $2(m_x + m_y) \lg(4en^2)$, respectively.

Proof  See Appendix B.

Fig. 2. Sample complexity bounds for non-strict BMIs, for $\delta = 1 \times 10^{-8}$, $m_x + m_y = 13$, and for different BMI dimensions: $n = 10$ (continuous line) $n = 50$ (dashed line) and $n = 100$ (dash-dotted line). The red plots show the two-sided bound, while the blue plots show the one-sided constrained failure bound for $\rho = 0$.

Remark 1 (Strict and Non-Strict LMIs/BMIs)  Comparing the bounds of Theorems 2 and 3, it can be seen that the bounds on the VC-dimension of strict and non-strict LMIs/BMIs differ only in the terms $n^2$ and $n2^n$ appearing in the arguments of the logarithm. That is, the quadratic dependence on $n$ of strict LMIs/BMIs becomes an exponential one for non-strict ones. Note however that this effect is largely mitigated by the logarithm. This difference is not surprising, and it follows from the fact that checking positive semi-definiteness requires non-negativity of all principle minors, as discussed in Appendix B. To see this, consider this simple counterexample presented in Bernstein (2009):
the matrix

\[
A = \begin{bmatrix}
1 & 1 & 1 \\
1 & 1 & 1 \\
1 & 1 & 0
\end{bmatrix}
\]

has leading principal minors equal to 1, 0 and 0, which are nonnegative. However, the matrix is not positive semidefinite as its eigenvalues are 2.732, 0, and −0.732. Note that the same issue arises in (Vidyasagar & Blondel, 2001, Theorem 4), regarding positive definiteness and semi-definiteness of interval matrices.

**Remark 2 (Explicit Sample Complexity)** Using the results of Theorem 3, we can establish bounds on sample complexity which guarantee the probability of two-sided failure and the probability of one-sided constrained failure of uncertain semidefinite LMI and BMI problems to be bounded by the confidence parameter \(\delta\). It should be noted that for semidefinite problems of this section, Definition 1 is revised accordingly such that strict inequalities in (4) and (5) are replaced with nonstrict ones. This also affects empirical violation, probability of two-sided failure and probability of one-sided constrained failure. Then, the results of Corollaries 1 and 2 for the uncertain semidefinite LMI and BMI problems immediately hold provided that the VC-dimension bounds \(2m_x \log(4en^2)\) and \(2(m_x + m_y) \log(4en^2)\) are replaced with \(2m_x \log(4en^2n)\) and \(2(m_x + m_y) \log(4en^2n)\) respectively. The behavior of the sample complexity bounds for semidefinite BMIs are illustrated in Figure 2.

It should be also noted that the sample complexity bounds derived in this paper for the uncertain strict and semidefinite LMI and BMI problems can be quite large. This is a usual situation in the context of statistical learning, that may lead to computationally expensive optimization problems if Algorithm 1 is applied in a batch way. This motivated the developments of the next section, where a sequential randomized algorithm for bounding the probability of one-sided constrained failure is presented. The sequential algorithm can alleviate the computational burden of directly solving (7).

6 Sequential Randomized Algorithm

Sequential methods in probabilistic design usually follow an iterative scheme which includes optimization steps to update the design parameters, followed by randomization steps to check the feasibility of the candidate solution (Tempo et al., 2013). The first step is deterministic, while the second one is probabilistic. Examples of such scheme are probabilistic design methods based on gradient, ellipsoid and cutting plane update rules, see Tempo et al. (2013) for more details.

Recently Alamo et al. (2012) introduced a general framework for nonconvex problems, defining the class of sequential probabilistic validation (SPV) algorithms. Motivated by this, in this section we propose a sequential randomized
algorithm specifically tailored for the problem at hand, which mitigates the conservatism of the bounds (14)-(15) or their corresponding sample bounds for the uncertain semidefinite LMI and BMI problems. This is accomplished by generating a sequence of “design” sample sets \( \{q_d^{(1)}, \ldots, q_d^{(N_k)}\} \) with increasing cardinality \( N_k \) which are used in (7) for solving the optimization problem. In parallel, “validation” sample sets \( \{q_v^{(1)}, \ldots, q_v^{(M_k)}\} \) of cardinality \( M_k \) are also generated by the algorithm in order to check whether the given candidate solution, obtained from solving (7), satisfies the desired violation probability or not. The proposed scheme is reported in Algorithm 2.

For simplicity of notation, we denote the sample bounds derived in Corollary 2 and the corresponding sample complexity for the uncertain semidefinite LMI and BMI problems by \( N_{MI} \).

**Algorithm 2 A Sequential Randomized Algorithm**

1. **Initialization**
   - Set the iteration counter to zero \( (k = 0) \). Choose the desired accuracy \( \varepsilon \in (0, 1) \), confidence \( \delta \in (0, 1) \) and level \( \rho \in [0, 1) \) parameters and the desired number of iterations \( k_t > 1 \).

2. **Update**
   - Set \( k = k + 1 \) and \( N_k = N_{MI} \).

3. **Design**
   - Draw \( N_k \) i.i.d samples \( q_d = \{q_d^{(1)}, \ldots, q_d^{(N_k)}\} \) from the uncertainty set \( \mathcal{Q} \) based on the underlying distribution.
   - Solve the following optimization problem
     
     \[
     \begin{align*}
     \min_{\theta} & \quad c^T \theta \\
     \text{subject to} & \quad \hat{V}_g(\theta, q_d) \leq \rho.
     \end{align*}
     \]

     (17)

   - **If** the optimization problem (17) is not feasible, the original problem is not feasible as well.
   - **Else if**, the last iteration is reached \( (k = k_t) \), \( \hat{\theta}_{N_k} \) is a probabilistic robust solution and **Exit**.
   - **Else**, continue to the next step.

4. **Validation**
   - Draw
     
     \[
     M_k > \frac{\alpha \ln k + \ln (\mathcal{S}_k(\alpha)) + \frac{1}{\alpha}}{\ln \left( \frac{1}{1+\varepsilon} \right)}
     \]

     (18)

     i.i.d. samples \( q_v = \{q_v^{(1)}, \ldots, q_v^{(M_k)}\} \) from the uncertainty set \( \mathcal{Q} \) based on the underlying distribution.
   - **If**
     
     \[
     \hat{V}_g(\hat{\theta}_{N_k}, q_v) \leq \rho
     \]

     then, \( \hat{\theta}_{N_k} \) is a probabilistic solution and **Exit**.
   - **Else**, goto step (2).

In the validation bound (18), the parameters \( a \geq 1 \) and \( \alpha > 0 \) are real and \( \mathcal{S}_k(\alpha) \) is a finite hyperharmonic series.
also known as $p$-series, that is

$$S_k(\alpha) = \sum_{k=1}^{k_t} \frac{1}{k^\alpha}.$$ 

The theoretical properties of Algorithm 2 are summarized in the next theorem, see Theorem 5 in Chamanbaz et al. (2013a) for proof.

**Theorem 4** Suppose $\epsilon, \delta \in (0, 1)$ are given. The, if at iteration $k$ Algorithm 2 exits with a probabilistic solution $\hat{\theta}_{N_k}$, then it holds that $V(\hat{\theta}_{N_k}) \leq \rho + \epsilon$ with probability no smaller than $1 - \delta$ that is

$$\Pr \left\{ V_g(\hat{\theta}_{N_k}) \leq \rho + \epsilon \right\} \geq 1 - \delta.$$ 

**Remark 3 (Related results)** Algorithm 2 follows the general scheme of other sequential algorithms previously developed in the area of randomized algorithms for control of uncertain systems, see Calafiore et al. (2014), and in particular Alamo et al. (2012, 2009); Chamanbaz et al. (2013b); Koltchinskii et al. (2000). However, we remark that the sample bound $M_k$ in Algorithm 2 is strictly less conservative than the bound derived in Alamo et al. (2012) because the infinite sum (Riemann Zeta function) is replaced with a finite sum, following ideas similar to those recently introduced in Chamanbaz et al. (2013b). This leads to a considerable improvement in the sample complexity. Another important difference is on how the cardinality of the design sample set $N_k$ appears in the sequential algorithm. In (Chamanbaz et al., 2013b, Algorithm 1), the constraints are required to be satisfied for all the samples extracted from the set $Q$ while, in Algorithm 2, we allow a limited number of samples to violate the constraints in (1) and (2), or their semidefinite versions, in both “design” and “validation” steps. Finally, we note that the sequential randomized algorithm in (Chamanbaz et al., 2013b, Algorithm 2) is purely based on additive and multiplicative Chernoff inequalities and hence may provide larger sample complexity than (18).

It should also be remarked that the optimal values of the constants $a$ and $\alpha$ depend on other parameters of the algorithm, such as the termination parameter $k_t$, the accuracy level $\epsilon$, and the level parameter $\rho$. Suboptimal values of $a$ and $\alpha$ for which the sample bound (18) is minimized for a wide range of probabilistic levels are $a = 3.05$ and $\alpha = 0.9$. Note also that for $\rho = 0$ the optimal value of $a$ and $\alpha$ are $a = \infty$ and $\alpha = 0.1$, and the bound (18) reduces to bound (12) in Chamanbaz et al. (2013b).

Finally, we point out that the termination parameter $k_t$ defines the maximum number of iterations of the algorithm which can be chosen by the user. For problems in which the bound $N_{MI}$ in Algorithm 2 is large, larger values of $k_t$ may be used. In this way, the sequence of sample bounds $N_k$ would start from a reasonably small number and would not increase dramatically with the iteration counter $k$. 
7 Numerical Simulations

We illustrate the effectiveness of the developed theory on a linear model of a robot manipulator joint taken from Kanev & Verhaegen (2000). The state-space model of the plant is given by

\[
\begin{align*}
\dot{x}(t) &= Ax(t) + Bu(t) \\
z(t) &= C_1 x(t) + D_{11} w(t) \\
y(t) &= C x(t) + D_{21} w(t)
\end{align*}
\]

where

\[
A = \begin{bmatrix}
0 & 1 & 0 & 0 \\
0 & 0 & c & 0 \\
0 & 0 & 0 & 1 \\
0 & -\frac{\beta}{I_{son}} & -\frac{c}{M^2 I_m} - \frac{c}{I_{son}} & -\frac{\beta}{I_{son}} \\
\end{bmatrix}, \quad
B = \begin{bmatrix}
0 \\
\frac{L_t}{MI_m} \\
0 \\
-\frac{L_t}{MI_m}
\end{bmatrix}, \quad
C = \begin{bmatrix}
0 & M & 0 \\
1 & 0 & 1 & 0
\end{bmatrix}, \quad
D_{21} = \begin{bmatrix}
1 \\
0
\end{bmatrix},
\]

\[
C_1 = \begin{bmatrix}
1 & 0 & 1 & 0
\end{bmatrix} \quad \text{and} \quad D_{11} = 1.
\]

We considered all plant parameters to be uncertain by 15%. The nominal values are given in Table 1. The objective is to design a static output feedback controller which minimizes the worst case \(H_\infty\) norm of the transfer function from the disturbance channel \(w\) to the controlled output \(z\). This problem can be formulated in terms of a bilinear matrix inequality (Leibfritz, 2004) of the form

\[
\begin{align*}
\text{minimize} \quad & \gamma \\
\text{subject to} \quad & X > 0, \\
& (A + BFC)^T X + X(A + BFC) X(B_1 + BF D_{21}) (C_1 + D_{12} FC)^T \\
& \quad \begin{bmatrix}
* & -\gamma & (D_{11} + D_{12} FD_{21})^T \\
* & * & -\gamma
\end{bmatrix} < 0 
\end{align*}
\]

where \(X = X^T \in \mathbb{R}^{4 \times 4}, F \in \mathbb{R}^{1 \times 2}\) and \(*\) denotes entries that follow from symmetry.

| Spring constant | $c$ | 130 |

Table 1
Nominal values of the plant parameters.

Algorithms 1 and 2 were implemented using the Randomized Algorithm Control Toolbox (RACT) [Tremba et al., 2008], and we used PENBMI [Kočvara & Stingl, 2003] for solving BMI optimization problems. The probability density functions of all 6 uncertain parameters was assumed to be uniform. The level parameter $\rho$ in all simulations was chosen to be zero ($\rho = 0$). A bound on the VC-dimension of the BMI problem (19) can then be computed using Theorem 2, taking into account that $m_x + m_y = 13$ (for the design variables $F$, $X$ and $\gamma$), and that $n = 6 + 4 + 1 = 11$. Applying Corollary 2, the corresponding $N_{\text{BMI}}$ bounds necessary for applying Algorithm 1 can be computed, and are reported in Table 2 (third column) for different values of $\delta$ and $\varepsilon$.

Clearly, these sample bounds are quite large. For this reason, we used Algorithm 2 to efficiently solve the problem.
Since the sample complexities $M_k$ and $N_k$ in which Algorithm 2 terminates are random variables, we run the simulations 100 times for each pair of probabilistic accuracy and confidence parameters. The mean, standard deviation and worst case values of the number of design samples, validation samples, objective value and the iteration number in which the algorithm exits are tabulated in Table 2. We conclude that with Algorithm 2 we can achieve the same probabilistic levels with a much smaller number of design samples.

8 Conclusions

In this paper, we computed explicit bounds on the Vapnik-Chervonenkis dimension (VC-dimension) of two problems frequently arising in robust control, namely the solution of uncertain LMIs and BMIs. In both cases, we have shown that the VC-dimension is linear in the number of design variables. These bounds are then used in a sequential randomized algorithm that can be efficiently applied to obtain probabilistic optimal solutions to uncertain LMI/BMI. Since the sample complexity is independent of the number of uncertain parameters, the proposed algorithm runs in polynomial time.

Acknowledgements

The results presented in this paper were obtained when the first author was visiting CNR-IEIIT for a period of six months under DSI funding.

A Proof of Theorem 2

First, we introduce the following definition.

**Definition 7** ($(\gamma, \eta)$-Boolean Function) The function $g : \mathbb{R}^{m_\theta} \times Q \to \{0, 1\}$ is a $(\gamma, \eta)$-Boolean function if for fixed $q$ it can be written as expressions consisting of Boolean operators involving $\eta$ polynomials

$$\beta_1(\theta), \ldots, \beta_\eta(\theta)$$

in the components $\theta_i$, $i = 1, \ldots, m_\theta$ and the degree of these polynomials with respect to $\theta_i$ is no larger than $\gamma$.

The following lemma (Vidyasagar, 2002) which is an improvement on the original result of Karpinski & Macintyre (1995), states an upper bound on the VC-dimension of $(\gamma, \eta)$-Boolean functions.

**Lemma 1** Suppose that $g : \mathbb{R}^{m_\theta} \times Q \to \{0, 1\}$ is an $(\gamma, \eta)$-Boolean function, then

$$\text{VC}_g \leq 2m_\theta \lg(4e\gamma \eta). \quad (A.1)$$
In view of this lemma, in order to find the VC-dimension of the uncertain LMI and BMI problems, it suffices to represent the constraints in (1) and (2) as polynomial inequalities. It is well known that an \( n \times n \) real symmetric matrix is positive definite if and only if all \( 2^n \) principal minors are positive. However, this condition is equivalent to checking positivity of all \( n \) leading principal minors.

Since LMIs are a special case of BMIs, we first prove Theorem 2 for the more general case of BMIs. Let \( F_{\text{BMI},ij}(x, y, q) \) be the \( ij \)-th element of the BMI in (2). The leading principal minors of \( F_{\text{BMI}}(x, y, q) \) are

\[
F_{\text{BMI},11}(x, y, q), \det \left( \begin{bmatrix} F_{\text{BMI},11}(x, y, q) & F_{\text{BMI},12}(x, y, q) \\ F_{\text{BMI},21}(x, y, q) & F_{\text{BMI},22}(x, y, q) \end{bmatrix} \right), \ldots, \\
\det \left( \begin{bmatrix} F_{\text{BMI},11}(x, y, q) & \cdots & F_{\text{BMI},1k}(x, y, q) \\ \vdots & \ddots & \vdots \\ F_{\text{BMI},k1}(x, y, q) & \cdots & F_{\text{BMI},kk}(x, y, q) \end{bmatrix} \right), \ldots, \det (F_{\text{BMI}}(x, y, q)).
\]

Since the number of leading principal minors is \( n \), we need to check \( n \) polynomial inequalities.

Next, we need to find the maximum degree of each polynomial inequality with respect to design variables \( x_i, i = 1, \ldots, m_x \) and \( y_j, j = i, \ldots, m_y \). Based on the definition of determinant, \( k \)-th leading principal minor of the BMI in (2) for \( k = 3, \ldots, n \) can be written as

\[
D_k = \sum_{\ell=1}^{k} (-1)^{\ell+1} F_{\text{BMI},\ell1}(x, y, q) M_{\ell1}
\]

where \( D_k \) is the \( k \)-th principal minor and \( M_{\ell1} \) is the \((\ell, 1)\) minor of a matrix formed by the first \( k \) rows and columns of the BMI in (2). Then, we can prove that the \( k \)-th leading principal minor has the maximum degree \( k \) with respect to the design variables. From the definition of the BMI in (2), it is clear that every element of the BMI, including the first leading principal minor, has maximum degree of 1 with respect to the design variables. The second leading principal minor of the BMI in (2)

\[
D_2 = F_{\text{BMI},11}(x, y, q) F_{\text{BMI},22}(x, y, q) - F_{\text{BMI},21}(x, y, q) F_{\text{BMI},12}(x, y, q)
\]

is a polynomial of maximum degree 2. For \( k > 2 \), the maximum degree of \( D_k \) in (A.2) is defined by the multiplication of \( F_{\text{BMI},11}(x, y, q) \) and \( M_{11} \). The former has the maximum degree of 1 and the latter has the maximum degree equal to \( D_{k-1} \) because they are of the same order. Hence, the maximum degree of the \( k \)-th leading principal minor with respect to the design variables for \( k = 1, \ldots, n \) is \( k \).
Therefore, checking positive definiteness of the BMI in (2) is equivalent to checking $n$ polynomial inequalities of degree ranging from 1 to $n$ which can be represented as an $(\gamma, \eta)$−Boolean function with $\gamma = \eta = n$. The result of Theorem 2 follows by substituting the obtained values of $\gamma$ and $\eta$ into (A.1). We notice that the same reasoning holds for the case of LMI and we can represent the LMI in (1) as an $(\gamma, \eta)$−Boolean function with $\gamma = \eta = n$.

### B Proof of Theorem 3

The result follows observing that an $n \times n$ symmetric matrix is positive semidefinite if and only if all $2^n$ principal minors are nonnegative. Then, following similar reasoning as in the proof of Theorem 2, we can show that checking positive semidefiniteness of (1) and (2) is equivalent to evaluating $2^n$ polynomial inequalities of degree ranging from 1 to $n$. This can be represented as $(\gamma, \eta)$−Boolean function with $\gamma = n$ and $\eta = 2^n$. The results of Theorem 3 follow by substituting the obtained values of $\gamma$ and $\eta$ in (A.1).
