Abstract

OBJECTIVES: Progressive root dilatation is an important complication in patients with transposition of the great arteries (TGA) after arterial switch operation (ASO) that may be caused by altered flow dynamics. Aortic wall shear stress (WSS) distribution at rest and under dobutamine stress (DS) conditions using 4D flow magnetic resonance imaging were investigated in relation to thoracic aorta geometry.

METHODS: 4D flow magnetic resonance imaging was performed in 16 adolescent TGA patients after ASO (rest and DS condition) and in 10 healthy controls (rest). The primary outcome measure was the WSS distribution along the aortic segments and the WSS change with DS in TGA patients. Based on the results, we secondary zoomed in on factors [aortic geometry and left ventricular (LV) function parameters] that might relate to these WSS distribution differences. Aortic diameters, arch angle, LV function parameters (stroke volume, LV ejection fraction, cardiac output) and peak systolic aortic WSS were obtained.
RESULTS: TGA patients had significantly larger neo-aortic root and smaller mid-ascending aorta (AAo) dimensions and aortic arch angle. At rest, patients had significantly higher WSS in the entire thoracic aorta, except for the dilated root. High WSS levels beyond the proximal AAo were associated with the diameter decrease from the root to the mid-AAo (correlation coefficient r = 0.54–0.59, P = 0.022–0.031), not associated with the aortic arch angle. During DS, WSS increased in all aortic segments (P < 0.001), most pronounced in the AAo segments. The increase in LV ejection fraction, stroke volume and cardiac output as a result of DS showed a moderate linear relationship with the WSS increase in the distal AAo (correlation coefficient r = 0.54–0.57, P = 0.002–0.038).

CONCLUSIONS: Increased aortic WSS was observed in TGA patients after ASO, related to the ASO-specific geometry, which increased with DS. Stress-enhanced elevated WSS may play a role in neo-aortic root dilatation and anterior aortic wall thinning of the distal AAo.

INTRODUCTION

The arterial switch operation (ASO) is the current treatment for patients with the transposition of the great arteries (TGA). This surgical intervention restores the ventriculo-arterial concordance by reconnecting the great arteries to the correct ventricles leaving the semilunar valves and the native root in its original position. The relocation of the great arteries following ASO results in an altered spatial great artery relationship and geometry of the thoracic aorta. With the Lecompte manoeuvre, the pulmonary artery bifurcation is positioned in front of the ascending aorta (AAo) with the pulmonary artery branches embracing the AAo, resulting in a more posterior location of the AAo post-ASO. Consequently, an acute angulation of the curvature of the aortic arch is often present after ASO [1, 2].

In the long term, progressive neo-aortic root dilatation occurs accompanied by an increasing incidence of neo-aortic valve leakage in these patients [3, 4]. Furthermore, cardiothoracic surgeons have observed thinning of the anterior wall of the AAo in adult post-ASO patients who underwent reoperation for the aneurysmatic neo-aortic root dilatation [5, 6], closely related to the location of the pulmonary arteries. It is largely unknown what mechanisms contribute to the progression of neo-aortic root dilatation and anterior wall thinning, but geometry-driven alterations in aortic flow might have its impact on the (neo)aortic wall. This relationship has been shown in bicuspid aortic valve-related aortopathy [7] but has not been extensively evaluated in TGA patients post-ASO so far [8].

With 4D flow magnetic resonance imaging (MRI), blood flow and haemodynamic parameters in large vessels can be visualized and quantified and this imaging modality facilitates studying the relation and interaction of aorta geometry and blood flow on the aortic wall [i.e. wall shear stress (WSS)]. Currently, almost all patients studies using 4D flow MRI have been performed in rest states. However, it is unknown how aortic blood flow haemodynamics behave with an increase in cardiac output (CO) and whether changes in stroke volume (SV) may add to changes in haemodynamic parameters. Low-dose dobutamine increases heart rate, myocardial contractility and ventricular ejection by stimulating β-1 receptors on the heart and allows studying aortic haemodynamics under increased SV conditions using MRI.

We hypothesize that evaluation of haemodynamics of the thoracic aorta reveals specific areas with abnormal WSS that increase under pharmacological-induced stress conditions and may help to better understand blood flow interactions on the aortic vessel wall in patients with repaired congenital heart diseases with altered aortic geometry. Therefore, the aim of this study was to evaluate aortic WSS in the thoracic aorta of patients with TGA after ASO with comparative rest and pharmacological stress 4D flow MRI investigations.

METHODS

Study population

The study protocol was approved by the local Medical Ethics Committee and informed consent was obtained from all patients and their legal guardians. Sixteen patients with TGA and intact ventricular septum or TGA and ventricular septal defect were prospectively included in the study between January 2016 and December 2017. Patients from outpatient paediatric and congenital cardiology clinics who needed a standard-of-care MRI of the heart and large vessels as regular clinical follow-up for early detection of well-known sequelae after ASO from the age of 10 years were invited to participate. To ensure morphological homogeneity, exclusion criteria were Tausig-Bing anomaly, prior left ventricular (LV) outflow tract obstruction, bicuspid neo-aortic valve, aortic arch obstruction, presence of branch pulmonary artery stent(s), moderate-to-severe neo-aortic insufficiency or prior neo-aortic valve or root reoperations. All patients underwent aortic 4D flow MRI at rest and during dobutamine-induced stress immediately following the standard-of-care MRI assessment. The healthy subjects were recruited from a prior 4D flow MRI validation study [9] and served as a reference group. They underwent...
the same MRI protocol including 4D flow aortic imaging (only at rest).

MRI acquisition

All MRI examinations were performed on a 3-T scanner (Ingenia, Philips Healthcare, Netherlands). The protocol included ECG-gated two-dimensional cine steady-state free precession imaging for ventricular and functional analysis at rest and during dobutamine stress (DS). At rest, a three-dimensional (3D) non-contrast enhanced magnetic resonance angiography (NCE-MRA) was performed for the assessment of thoracic aorta diameters and aortic arch geometry. 4D flow MRI covering the thoracic aorta was acquired at rest and during DS condition. MRI acquisition details are summarized in Supplementary Material, Table S1. Dobutamine was administered intravenously starting at a dose of 5.0 μg/kg/min, and the dose was increased to 7.5 μg/kg/min after 3 min followed by a 5–10 min observation period waiting for a steady state of patients’ heart rate and blood pressure.

Aortic geometry and cardiac function

LV indices [LV end-systolic volume (LVESV) and LV end-diastolic volume (LVEDV)] and LV function parameters [SV, LV ejection fraction (LVEF), CO and cardiac index] were obtained from short-axis steady-state free precession images: stroke volume = LVEDV – LV end – systolic volume; LVEF = 100 × stroke volume / LVEDV, CO = SV × heart rate; cardiac index = CO / body surface area.

Aortic diameters were measured from NCE-MRA at 6 anatomic landmarks: (i) neoaortic root (Root); (ii) sinotubular junction, defined as the aortic level 5–7 mm below the pulmonary artery bifurcation; (iii) mid-AAo at the level of the pulmonary artery bifurcation (mid-AAo); (iv) aorta at the origin of the innominate artery; (v) aortic isthmus; and (vi) mid-descending aorta (DAO) (Fig. 1A and B). Aortic dimensions were measured from external-to-external edges from a sagittal-axis orientation. Average neoaortic root diameters (average of 3 cusp-to-commissure dimensions) were measured perpendicular to the aortic axis on NCE-MRA double oblique transversal angulated multplanar reconstructions. Diameters were indexed to body surface area and converted into Z-scores [10]. Aortic diameter ratio between the neoaortic root diameter and the mid-AAo diameter was calculated 

Aortic arch geometry was obtained from NCE-MRA. After aortic segmentation using Enterprise Suite v6.5 (Vital Images, Minnetonka, MN, USA) and automatic computation of the centreline of the aorta segmentations, the aortic arch width (w), maximal height (h, perpendicular to the width) and aortic arch angle (α, between mid-AAo, maximal height and mid-DAO) were quantified (Fig. 1C and D) using an in-house developed software (Python Software Foundation, Wolfeboro Falls, NH, USA). Width-height (w/h) ratio was calculated accordingly.

Segmental WSS assessment

The software programme CAAS MR 4D flow v2.0 (Pie Medical Imaging BV, Maastricht, Netherlands) was used for post-processing of the 4D flow MRI data, for which a 3D WSS reproducibility analysis study showed robustness of the segmentation and WSS analysis method [9]. A summary of the workflow analysis is depicted in Fig. 1E–H and was previously described in detail [9]. Briefly, from the 4D flow dataset peak systolic thoracic aortic segmentations were performed and provided with an aortic centreline (Fig. 1E and F). For the regional aortic WSS assessment, the thoracic aorta was manually subdivided into 5 segments based on anatomic landmarks by placing planes perpendicular to the aortic centreline (Fig. 1G): segment 1: proximal AAo (pAAo, from aortic valve level to mid-AAo); segment 2: distal AAo (dAAo, from mid-AAo to innominate artery); segment 3: aortic arch (Arch, from the innominate artery until left subclavian artery); segment 4: proximal DAO (beyond the left subclavian artery to the mid-descending thoracic aorta); and segment 5: distal DAO (from mid-descending thoracic aorta to the DAO at the level of the aortic valve). For every aortic segment, mean 3D systolic WSS (WSSmean) and maximum 3D systolic WSS (WSSmax) values were calculated as described previously (Fig. 1H) [9]. WSS is defined as the derivative of the axial velocity μ at the vascular wall in the direction perpendicular to the vascular wall times the dynamic viscosity μ [WSS = μ ∂v/∂n (in mPa)]. The surface of the 3D segmented aorta was divided into wall points, and for all wall points, a 3D systolic WSS vector was calculated based on a quadratic approximation of the axial velocity profile perpendicular to the surface of the 3D segmented aorta [9]. WSSmax was then defined as the maximum WSS vector of all wall points within the defined aortic segment (in mPa). WSSmean was defined as the average of all WSS vectors of all wall points within the defined aortic segment (in mPa). Differences in WSS (ΔWSS) and percentage WSS changes (%WSS) between rest and stress state were calculated for each segment: ΔWSS = WSS stress – WSS rest and %WSS = (WSS stress – WSS rest) / WSS rest

Statistical analysis

Statistical analyses were performed using IBM SPSS Statistics version 23 (IBM, Chicago, IL, USA). Variables are presented as mean ± standard deviation or median (interquartile range) depending on the normality of the distribution. The normality of the distribution was tested using the Shapiro–Wilk test. The primary outcome measure was the WSS distribution along the aortic segments and the WSS change with DS in TGA patients. Based on the results, we secondary zoomed in on factors (aortic geometry and LV function parameters) that might relate to these WSS distribution differences. A power calculation was performed to determine the power to detect differences in the WSS values between the rest and DS measurements (primary outcome measure). Based on the WSS magnitude known in the healthy paediatric and adult population, study sample sizes to show a 20% difference (difference of clinical interest; estimated mean difference in WSSmean 400 Pa; estimated standard deviation 100 Pa) in these variables with a power of 90% and an α error of 0.01 (to correct for multiple comparison according to the Bonferroni correction) must contain a minimum of 6 TGA patients. The power analysis was performed for the paired t-test (because of the unknown shape of the underlying distribution) (Division of Biomathematics/Biostatistics, Columbia University Medical Center, New York, USA; http://biomath.info/power). Using the rule of thumb because of using a non-parametric test, we added 15% to the sample size required for a parametric test, resulting in a study sample size of at least 7–8 patients.
A chi-square test was performed to investigate differences in sex distribution between TGA patients and healthy subjects. Differences between groups were compared using the independent sample t-test or a Mann–Whitney test based on the normality of the distribution. Differences in cardiac parameters between rest and DS were tested by a paired t-test; in case of non-normality, the Wilcoxon signed-rank test was performed. A Friedman test was performed to test for differences in the percentage increase in WSS from rest to stress state between the 5 aortic segments. A Bonferroni correction was performed to adjust for the multiple comparisons for the WSS analysis along aortic segments between groups, between rest and DS in TGA patients and for the percentage WSS increase from rest to stress between the 5 aortic segments. Correlation between aortic geometry measures (root/mid-AAo diameter ratio, arch angle and w/h ratio) and segmental aortic WSS were calculated using Spearman rank correlation. Correlation between percentage WSSmean increase and percentage increase in LV function parameters [ejection fraction (EF), SV, CO] were calculated using Pearson’s correlation. A P-value of <0.05 was considered statistically significant.

RESULTS

Aortic geometry

Patient characteristics are shown in Table 1. Indexed neoaortic root and sinotubular junction dimensions (Z-scores) were significantly larger in TGA patients compared to healthy subjects. Neoaortic root and sinotubular junction were dilated (Z-score >2.0) in 94% and 81% of the TGA patients, respectively. Patients without aortic Z-score >2.0 had also large indexed neoaortic root and sinotubular junction dimensions with Z-scores ≥1.7, except for 1 patient. The mid-AAo diameter was significantly smaller in TGA patients. Other thoracic aortic dimensions were within the normal range compared with the MRI-based healthy reference population (Z-score <2.0). Aortic arch geometry descriptors showed that the aortic arch height was comparable between TGA patients and healthy subjects. The aortic arch angle, aortic width and w/h ratio were significantly smaller in TGA patients.

Thoracic aortic WSS at rest and correlation with geometry

Figure 2A and B illustrates the aortic WSS along the entire thoracic aortic segments and shows the regional differences in WSSmean and WSSmax between TGA patients and healthy subjects. At rest, TGA patients showed significantly higher WSS in almost all thoracic aortic segments (P < 0.001—P = 0.015), except for the pAAo segment (for WSSmean and WSSmax) and proximal DAO (for WSSmean) (Fig. 2A and B). In TGA patients, WSS magnitude (WSSmean and WSSmax) was lowest in the dilated pAAo while the highest WSSmax levels were found in the dAAo segment. Along the thoracic aorta, the trend (i.e. increase or decrease) of the WSSmean and WSSmax between the aortic segments also differed between TGA patients and healthy...
In the healthy subjects, there was a WSS decrease from the pAAo segment to the aortic arch segment, with a WSS increase beyond the aortic arch (Fig. 2A and B). In TGA patients, there was a significant WSS increase from the pAAo segment to the dAAo segment ($P < 0.001$ for WSSmean; $P = 0.003$ for WSSmax) with a concomitant WSS decrease in the aortic arch segment compared with the dAAo segment (Fig. 2A and B). Beyond the aortic arch, in the descending thoracic aorta, there was overall an increase in WSSmean and WSSmax between the consecutive segments comparable to the trend found in healthy subjects, but on a higher WSS level.

At rest, WSSmean in the dAAo segment, but also in the descending aortic segments, showed a moderate linear relationship with the change in aortic dimension between the neo-aortic root and mid-AAo, as expressed as the root/mid-AAo ratio (Fig. 3). A higher systolic WSSmean was detected in the patients with relatively small mid-AAo diameters compared with the neo-aortic root dimensions. In general, the aortic arch geometry descriptors, arch angle and $w/h$ ratio, did not show a relationship with the WSS parameters from the aortic arch and descending aortic segments (Supplementary Material, Table S2). Only for WSSmax in the distal DAo segment, an association was observed with the arch geometry (angle: correlation coefficient $r = 0.58$, $P = 0.020$ and $w/h$ ratio: correlation coefficient $r = 0.54$, $P = 0.032$).

### DS-induced changes in LV function parameters

At rest, no significant differences between TGA patients and healthy subjects were observed in cardiac parameters, except for heart rate and cardiac index (Supplementary Material, Table S3). All patients received maximum dobutamine dosage (7.5 µg/kg/min) without any adverse effects. In the entire TGA group, heart rate, blood pressure and the LV functional parameters derived from MRI, SV and CO, significantly increased from rest to stress state (Supplementary Material, Table S3). Fourteen TGA patients had a normal systolic LV function (EF ≥ 55%) and 2 patients...
slightly below normal (EF 51% and 54%) without regional wall motion abnormalities. No significant neoaortic regurgitation was present in the patients. All healthy subjects had an EF of ≥55%.

**Stress-induced changes in aortic WSS and correlation with LV function parameters**

During DS, the trend in WSS between the aortic segments remained similar but with significantly higher WSS in all aortic segments compared with the levels at rest state ($P < 0.001$—$P = 0.009$, for WSSmax and WSSmean) (Fig. 2A and B). The highest absolute WSSmean and WSSmax values were detected in the dAAo segment. The percentage WSS increase from rest to stress state was highest for the ascending aortic segments (pAAo and dAAo) with a WSS increase between 56–78% (Fig. 2C). The percentage WSS increase was the most pronounced for WSSmax and high but to a lesser extend present for WSSmean (for pAAo and dAAo: WSSmax 78% and 76%; WSSmean 58% and 56%, respectively). The dobutamine-induced percentage WSS increase diminished for the consecutive aortic segments beyond the ascending aortic segments (Fig. 2C).

All TGA patients showed more or less similar WSS patterns with an increased WSS area at the anterior wall of the dAAo segment, on top of the anterior root. This area of high WSS was present at rest and during DS and the area of high WSS also extended over the anterior wall of the dAAo (Fig. 4, example of single patient). The WSS distribution in the dAAo segments was asymmetric and more expressed on the anterior wall, and more symmetrically distributed over the aortic wall of descending aortic segments as suggested by the lower magnitude of WSSmax and the higher magnitude of WSSmean in the descending aortic
segments as compared with the ascending aortic segments (Fig. 2A and B).

The percentage increase in peak systolic WSSmean in the dAAo segment with stress showed a moderate positive linear relationship with the percentage increase in parameters EF, SV and CO as a result of dobutamine (Fig. 5). CO and EF showed the best association with the percentage increase in WSSmean (correlation coefficient $r = 0.59$, $P = 0.016$ and correlation coefficient $r = 0.70$, $P = 0.002$, respectively). Arch geometric descriptors did not show significant associations with WSS in aortic segments during DS (Supplementary Material, Table S2).

**DISCUSSION**

This study evaluated the thoracic aortic WSS in TGA patients after ASO. The effect of pharmacological-derived stress on aortic WSS was studied in vivo and was compared with the rest state. The main findings of this study demonstrate that patients after ASO have a significantly higher WSS magnitude in the entire thoracic aorta compared with healthy subjects at rest, except for the dilated pAAo. The regions of high peak systolic WSS were most pronounced in the dAAo and located at the anterior aortic wall of that segment. The specific ascending aortic geometry post-ASO, reflected by the size discrepancy between the dilated neo-aortic root and the smaller mid-AAo diameter, was associated with higher WSS levels in the aortic segments downstream this calibre change: the larger the size discrepancy, the higher the WSS levels in the dAAo, but also in the descending aortic segments. In addition to this association, the geometry of the aortic arch did not further contribute to the high WSS levels in the aortic arch and the ascending aortic segments. In addition to this association, the geometry of the aortic arch did not further contribute to the high WSS levels in the aortic arch and the ascending aortic segments. Dobutamine-induced cardiac stress did increase WSS magnitude significantly along all thoracic aortic segments, the most prominent in the AAo. The highest peak systolic WSS was present in the dAAo segment during both rest and stress, but for stress, this was even more pronounced. The peak systolic WSS increase by dobutamine in that segment showed a positive correlation with the increase in the LVEF, SV and CO.

The results of this study extend the findings reported previously [8]. In addition to the increased WSS in the dAAo segment, significantly higher WSS values at rest were observed in the aortic segments beyond the dAAo (the arch and descending aortic segments), segments of the aorta remote from the dilated neo-aortic root and not directly affected by the surgical repair. The increased WSS in these descending aortic segments is most likely a perpetuation of the elevated WSS found in the dAAo segment owing to the eccentric aortic outflow [8] and the abnormal ascending aortic geometry. This is supported by the observed relationship between the ascending aortic geometry and WSS in the descending thoracic aortic segments in this study. Local geometric changes in the aorta (i.e. changes in diameter, arch curvature, vessel torsion) are known to have effect on downstream haemodynamics [11]. In accordance with the existing literature [1, 2], TGA patients in this study showed a more acute aortic arch angulation. However, the aortic arch geometry descriptors (angle and $w/h$ ratio) were not associated with the high WSS magnitude in the aortic arch and descending aortic segments, on top of the aforementioned association with the ascending aortic geometry. This could also be related to the lack of power due to the relatively small sample size of TGA patients.

Impaired aortic bioelastic aortic wall properties have been described after ASO for TGA [12] and may also affect the blood flow propagation in the thoracic aorta (i.e. higher velocity), but...
extracellular matrix in the aortic wall [7, 16]. In healthy sub-
teration (thinning and degeneration) and dysregulation of the
long run as increased WSS is associated with elastic fibre al-

these factors were not investigated in this study. In thoracic aor-
tas of healthy volunteers, it has been reported that there is a sig-
nificant slowing of blood flow velocity in the aortic arch

two investigators, compared with the velocity in the AAo followed by an increase to higher velocities in the DAo due to vessel diameter reduction
[13]. As WSS is a derivative of velocity, these observations are in

Aortic WSS during DS

Low-dose dobutamine administration resulted in a normal car-
diac haemodynamic response in the TGA patients. Similar to pre-
vious findings from echocardiographic and MRI studies in

Clinical implications of the altered WSS distribution over the
aorta and the changes during stress are preliminary and conse-
quences unknown, as we did not evaluate the effect of it on the
aortic wall tissue itself. Correlation studies between 4D flow MR-
derived aortic WSS and aortic vessel specimen after neoaortic
root and/or ascending aortic replacement are important next
steps to consider. Furthermore, serial 4D flow MR evaluations
are essential to assess the predictive value of haemodynamic param-
eters such as WSS on the progression of aortic dilatation, wall
thinning or the development of adverse aortic events (aortic
dissection or rupture). Ultimately, comparative haemodynamic
studies between TGA patients after ASO performed with different
techniques (i.e. conventional ASO with versus without Lecompte
manoeuvre and conventional ASO versus spiral ASO technique)
may provide insights for the optimization of surgical strategies
for patients with different anatomy. Currently, based on our
study, clinical recommendations related to these issues are not
yet possible.

Limitations

The study is limited by the small sample size but represents ran-
domly selected TGA patients from the outpatient clinic that
required MR investigation as regular part of their regular lifelong
follow-up. Furthermore, healthy subjects in this study were older
compared with the TGA patients. As the velocity of aortic blood
flow is known to decrease with increasing age [19], older age
could have lowered the WSS results in healthy subjects since it is
a derivative of velocity. However, no large differences in mean
velocity and thus in WSS are to be expected based on the small
differences in age range between the groups based on a study on
the velocity distribution in the normal aorta over age [19]. The
comparison of the effect of pharmacological-induced stress on
the aortic WSS could not be performed other than within the
TGA group.

Figure 5: Correlation between increase in WSSmean in the distal ascending aorta and ejection fraction, stroke volume and cardiac output under dobutamine infusion. Pearson correlation coefficient (r). AAo: ascending aorta; CO: cardiac output; EF: ejection fraction; SV: stroke volume; WSS: wall shear stress.
CONCLUSION

In conclusion, increased aortic WSS was found in the distal ascending aortic segment and in the aortic segments beyond and was primarily related to the ASO-specific geometry of the AAo, not related to the steeper arch geometry. Dobutamine-induced stress further increased abnormal segmental WSS and showed a moderate positive correlation with the increase in LV CO parameters. Pharmacological-induced stress evaluations of aortic blood flow may better reflect location and expansion of vascular wall areas exposed to abnormal WSS with subsequent risks for vascular remodelling. Stress might play a role in neo-aortic root dilatation in TGA patients after ASO given the significant stress-induced WSS increase in the neo-aortic root, acting on root tissue with structural vessel wall abnormalities.
