Performance vector controlled direct torque induction motor drive using space vector modulation strategy

**Purpose.** The main objective of this work is to demonstrate the advantages brought by the use of space vector modulation technique in the direct torque control of the induction motor. To achieve this purpose, two different direct torque control approaches (with space vector modulation) are proposed and studied from a comparative aspect with each other and with the conventional direct torque control. The novelty of this work consists in the employment of an Integral-Proportional (IP) speed controller in the two proposed direct torque control approaches and a more in-depth evaluation for their performance mainly the switching frequency of inverter switching semiconductor components and motor torque ripple. These two different direct torque control approaches that use the space vector modulation strategy and/or fuzzy-logic control, are described in detail and simulated with IP speed controller. The simulation experiments are carried out using Matlab/Simulink software and/or fuzzy-logic tools. Results. Practical value. Comparison results show that the two proposed direct torque control approaches (with space vector modulation) exhibit a large reduction in torque ripples and can also avoid random variation problem of switching frequency (over a wide range of speed or on the other hand, the use of IP speed regulator ensured good dynamic performance for the drive system as well as considerably minimized peak overshoot in the speed response. Practically all of these benefits are achieved while retaining the simplicity and the best dynamic characteristics of the classical direct torque control, especially with the modified direct torque control approach in which the design or implementation requires minimal computational effort. References 23, tables 4, figures 17.

Key words: induction motor drive, direct torque control, voltage source inverter, space vector modulation, IP controller, fuzzy control.

**Introduction.** Three-phase induction motors have been widely used in industrial applications due to their low maintenance, high robustness, simple structure and high efficiency. In fact, in high performance applications such as motion control of an induction motor (IM), it is generally desirable that motor can provide a good dynamic torque response as it’s in DC motor drive. In order to achieve this objective, many researchers have focused on developing several control algorithms. Recently, an innovative control method, called Direct Torque Control (DTC) is introduced because of its capability to produce a fast torque control for the IM without to use much on-line computation as it’s in field oriented control [1-13].

Indeed, the main advantages offered by DTC are:
- Excellent torque dynamic with minimal response time;
- robustness against rotor parameters variation;
- decoupled control between the torque and stator flux;
- no need of voltage modulator;
- control method without inherent speed sensor.

These merits are counterbalanced by some drawbacks like:
- Possible problems either when starting the machine, or running at low speed or changing the load torque;
- requirement for torque and flux estimation which includes machine parameters identification;
- inherent ripples in the torque and stator flux;
- greater harmonic distortion in stator voltages and waveforms of currents;
- inverter switching states remain unchanged in a number of sample cycles. Thus, the switching frequency is not constant and inverter power components capacity will not be wholly utilized;
- acoustical noise produced because of random inverter switching frequency variation [1-4], [14-18].

To overcome these problems, a variety of techniques with different concepts are described in the literature. Some of diverse proposed solutions include DTC with; space vector modulation, various power converter topologies such as: multi-level inverter and matrix converter, sensorless...
control methods, optimal stator flux estimation for high speed operation and artificial intelligence techniques (fuzzy or neuro controllers) [1, 2, 4-8, 14-21]. These methods achieve certain improvements such as reduction of torque ripples and fixed switching frequency operation. However, control system complexity is greatly increased.

The goal of the paper. In order to solve problems, of ripples in both electromagnetic torque and stator flux and of random variation of inverter switching frequency, we have proposed and study in this work two different Direct Torque Control approaches making use of Space Vector Modulation technique (DTC-SVM) and/or fuzzy logic control.

Practically, fuzzy logic is considered as an interesting alternative approach for its advantages such as: analysis close to exigencies of users, ability of nonlinear systems control, best dynamic performances and inherent quality of robustness. On the other hand, SVM strategy uses a digital algorithm to obtain an appropriate switching states sequence for Voltage Source Inverter (VSI) control. Thus, inverter can generate an output voltage vector which is closest to its reference voltage vector, with a previously imposed switching frequency. Also, in conventional DTC a single voltage vector is applied throughout the sample time. Therefore, for small torque errors, motor torque may exceed its upper or lower limit. Instead, with SVM strategy, which uses more than one vector during sample period, torque ripples can be reduced.

Subject of investigations. First proposed DTC
SVM approach, called Direct Fuzzy Torque Control (DFTC), is introduced with the aim of reducing ripples of electromagnetic torque and stator flux and improving stator currents waveform. The so-called DFTC uses both SVM technique and hysteresis comparators. In this approach, a look-up table decides angle choice of voltage vector applied to the motor, while an estimator based on fuzzy logic calculates the amplitude of this vector. Thus, reference voltage vector will be synthesized using the space vector modulation.

The second DTC-SVM approach, named Modified Direct Torque Control (MDTC), uses an efficient algorithm, based on direct stator flux control, to independently control amplitude and position of reference stator flux vector of the IM. In fact, the proposed algorithm of MDTC structure is designed to calculate reference voltage vector amplitude leading to an optimal torque and stator flux control.

Performances of these two DTC-SVM approaches are demonstrated by simulation using Matlab/Simulink software and/or fuzzy logic tools. Simulation results are compared to those of classical DTC with the use of an IP controller in all studied DTC structures. Systems performances evaluation is carried out mainly based on: inverter switching frequency, dynamic responses of torque/speed and flux, ripples content in torque and stator flux and distortion of stator currents or stator voltages. The comparison results illustrate clearly the effectiveness and superiority of the proposed DTC-SVM approaches over conventional DTC.

Modeling of the induction motor and voltage source inverter. In order to properly design or simulate a control structure, mathematical model of the latter must be considered [4, 11, 12, 16]. So, under the usual assumption of no hysteresis, no eddy currents and no space harmonics, electrical model of IM can be expressed (in a stationary reference frame) by the following nonlinear equations:

$$
\begin{align*}
V_S &= R_s \cdot i_s + \frac{d\phi_s}{dt}, \\
V_r &= R_r \cdot i_r + \frac{d\phi_r}{dt} - j \cdot \omega \cdot \phi_r; \\
\phi_s &= L_s \cdot i_s + L_m \cdot i_r; \\
\phi_r &= L_r \cdot i_r + L_m \cdot i_s,
\end{align*}
$$

where \(R_s, L_s, R_r, L_r\) are the resistances and cyclic inductances of stator and rotor respectively; \(V_s, V_r, \phi_s, \phi_r\) are the voltage, current and flux vectors of stator and rotor respectively; \(L_m, \omega\) are the mutual inductance and electric motor speed (or rotor frequency).

The electromagnetic torque is expressed as a function of the stator and rotor fluxes

$$
\Gamma_e = \frac{3}{2} \cdot p \cdot \frac{L_m}{\sigma \cdot L_s \cdot L_r} \cdot \left( \phi_s \times \phi_r \right),
$$

where \(p\) is the number of pairs of poles and \(\sigma = 1 - \frac{L_m^2}{L_s \cdot L_r}\) is the motor dispersion coefficient.

Elimination of \(i_s\) and \(i_r\) from (1) and (2), gives the state form model of the induction machine with the stator and rotor fluxes as state variables and \(\tau_s = L_s/R_s\), \(\tau_r = L_r/R_r\) are the stator and rotor time constants respectively.

$$
\frac{d\phi_s}{dt} = \left[ \frac{1}{\sigma \cdot \tau_s} - \frac{L_m}{\sigma \cdot \tau_r \cdot L_s \cdot j \cdot \omega} \right] \cdot \frac{\phi_s}{\phi_r} + \left[ \frac{1}{\sigma \cdot \tau_r} \right] \cdot \frac{V_s}{\phi_r},
$$

The mechanical mode, associated with the rotor motion, is described by:

$$
J \cdot \frac{d\Omega}{dt} + f \cdot \Omega = \Gamma_e - \Gamma_r \left( \Omega \right),
$$

where \(\Gamma_e\) and \(\Gamma_r\) are respectively the load torque and electromagnetic torque developed by the machine; \(J, f\) and \(\Omega\) are the respectively inertia, friction coefficient and mechanical rotation speed (\(\Omega = \omega / p\)).

Figure 1 reveals the diagram of a typical three-phase VSI [4, 9, 10, 13, 22]. Here semiconductors are considered as ideal switches and \(S_a, S_b, S_c\) are switching states of each leg of this inverter. Relationships between switching states and phase output voltages \((V_{an}, V_{bn}, V_{cn})\) can be expressed as below:

$$
\begin{align*}
V_{an} &= V_{dc} \cdot \frac{2}{3} \cdot -1 \cdot -1 \cdot S_a, \\
V_{bn} &= V_{dc} \cdot \frac{1}{3} \cdot -1 \cdot -1 \cdot S_b, \\
V_{cn} &= V_{dc} \cdot \frac{1}{3} \cdot -1 \cdot -1 \cdot S_c,
\end{align*}
$$

where \(n\) is the neutral point of inverter load.

As it is well known, two-level voltage inverter has in principal eight possible combinations for its switching states. Where two of these combinations are termed as zero vectors and they are designated homogeneously as state 0 (\(V_a = V_b = V_c = 0\)), as their effects are equal.
The remaining six states represent stationary vectors in the complex \(\alpha - \beta\) plane (Fig. 2).

These six active state vectors can be expressed as follows:

\[
\vec{v}_k = \frac{2}{3} V_{dc} \cdot e^{j(k-1)\frac{\pi}{3}}, \quad k = 1, 2, ..., 6,
\]

where \(V_{dc}\) is the DC-link voltage.

This equation shows that the amplitude of each active vector is \((2/3) \cdot V_{dc}\) with a deviation angle of \(\pi/3\) between the different active vectors, thus building a regular hexagon with two zero vectors which are located at its origin (Fig. 2).

**Basic concepts of DTC.** The basic configuration of conventional DTC, proposed by Takahashi, is shown in Fig. 3.

It consists of a pair of hysteresis comparators, torque and flux estimators, phase vector selector and a two-level VSI. The fundamental idea of DTC is to choose the most appropriate voltage vector which allows simultaneous and independent control of stator flux and electromagnetic torque, thus ensuring decoupled control for these two machine quantities. In fact, the performance of this control technique depends directly on the estimation of torque and stator flux so that an incorrect estimation will result in a wrong selection of inverter state vectors [1-8, 14, 16-18, 20, 21, 23].

Mainly in DTC technique, torque and stator flux estimation can be done by means of measurement; of two or three different phase currents \((i_{Sa}, i_{Sb}, i_{Sc})\) and of DC-link voltage. In fact, estimation procedure is carried out using the following equations:

\[
\begin{align*}
    i_{Sa} &= i_{Sa}^*; \\
    i_{Sb} &= \frac{1}{\sqrt{3}} (i_{Sb} - i_{Sc}); \\
    v_{Sa} &= \frac{2}{3} V_{dc} \cdot (S_a - S_b + S_c); \\
    v_{Sb} &= \frac{1}{\sqrt{3}} V_{dc} \cdot (S_b - S_c).
\end{align*}
\]

Estimated stator flux is then given by:

\[
\begin{align*}
    \hat{\phi}_{Sa} &= \int (v_{Sa} - R_S \cdot i_{Sa}) dt; \\
    \hat{\phi}_{Sb} &= \int (v_{Sb} - R_S \cdot i_{Sb}) dt,
\end{align*}
\]

where \(v_{Sa,b}, i_{Sa,b}\) and \(\hat{\phi}_{Sa,b}\) are the two \(\alpha - \beta\) components of stator voltage, current and estimated flux respectively.

The electromagnetic torque is estimated on-line by knowledge of instantaneous values of direct and quadratic components of the stator flux and stator current:

\[
\hat{\tau}_e = \frac{3}{2} p \cdot \hat{\phi}_{Sa} \cdot i_{Sb} - \hat{\phi}_{Sb} \cdot i_{Sa}.
\]
part is in the feedback path and the proportional part is in the feedforward path.

Fig. 4. Speed control loop with IP regulator

**Direct Fuzzy Torque Control (DFTC).**

The corresponding structure of DFTC employs space vector modulation strategy as shown in Fig. 5. In this case, flux and torque errors are used as two inputs either to fuzzy logic estimator of reference voltage vector amplitude \( |V_S^*| \) or to hysteresis comparators that deliver errors levels \((C_f, C_{fe})\) which are used for determining \( V_S^* \) position (via a lookup table).

Unlike the conventional DTC technique, where the applied voltage vector has constant amplitude even if the motor torque is outside its hysteresis band, DFTC structure allows the calculation of an optimum voltage, which will be used in the control of IM, according to the states of torque and stator flux in relation to their desired values. Thus providing a fast and accurate control of the electromagnetic torque. In fact, this optimal voltage vector is synthesized using SVM block which generates the most appropriate switching states to the inverter \([3,14,16,23]\).

In this DTC approach, the reference voltage vector position relative to the stator flux vector must be chosen so as to maintain the stator flux and electromagnetic torque in an optimal error band around their respective reference values. Indeed, the position of this voltage vector \((\delta_S)\) is obtained by adding an angle \((\delta)\) to the position of stator flux \((\theta_S)\) such as:

\[
\delta_S = \delta + \theta_S.
\]

The angle \(\delta\) is selected based on hysteresis comparators output values as depicted in Table 2. It should be noted here, that both hysteresis regulators of torque and stator flux are three levels comparators.

| Selection of the stator voltage vector position | \( C_{fe} \) | \(-1\) | \(0\) | \(1\) |
|-----------------------------------------------|----------|------|------|------|
| \( C_f \) | \(-1\) | \(0\) | \(1\) | \(-1\) | \(0\) | \(1\) |
| \( \delta \) | \(-2\pi/3\) | \(+2\pi/3\) | \(-\pi/3\) | \(+\pi/3\) | \(-\pi/2\) | \(+\pi/2\) | \(-\pi/2\) | \(+\pi/2\) | \(-\pi\) | \(+\pi\) |

Also, reference voltage vector amplitude must be chosen so as to reduce flux and torque errors. Thus, a fuzzy logic estimator (FLE) is designed to generate the most appropriate amplitude of the reference voltage vector. Proposed estimator block diagram, that combines «fuzzification – rules base – defuzzification» modules, is given in the Fig. 6.

In fuzzification module, inputs are crisp physical signals \((\tilde{e}_t, \tilde{e}_\phi)\) of real process and outputs are fuzzy subsets consisting of intervals and membership functions \((\tilde{c}_{fe}, \tilde{c}_f)\). These outputs will be inputs for the next module, fuzzy logic IF-THEN rules base of control, which requires fuzzy-subset inputs in order to be compatible with fuzzy logic rules \([15,18,19,22]\).

The general procedure in designing a fuzzy logic rules base includes the following:

- defining process states and control variables;
- determining input variables to inference engine block;
- forming a fuzzy logic IF-THEN rules base (determined input variables in previous step will be used in rules base design);
- establishing a fuzzy logic inference engine.

In fact, this latter phase explains how FLE decides on an optimal reference voltage vector amplitude \(|V_S^*|\) based on the control rules and linguistic terms. In general, inference systems have two types, namely Mandani and Takagi-sugeno \([18,21,22]\). Mandani method is used in this study because of its simple structure and design. Fuzzy rules consist of IF-THEN linguistic terms, and output membership functions are operated by fuzzy rules that are related to both inputs \((\tilde{e}_t, \tilde{e}_\phi)\) and output \(|V_S^*|\). Inference engine block, based on input fuzzy variables uses forty-nine IF-THEN rules, where AND method corresponds to minimum fuzzy inputs, in order to obtain final output fuzzy sets as shown in Table 3. These rules are setting in turn to take maximal amplitude for voltage vector, when torque is outside its error band. Otherwise, zero amplitude is assigned to this voltage vector.

| Complete rules base for the proposed FLE |
|------------------------------------------|
| \( \tilde{e}_t \) & \( \tilde{e}_\phi \) & NH & NM & NS & ZE & PS & PM & PH |
| NH & PH & PM & PS & PS & PS & PM & PH |
| NM & PH & PM & PS & PS & PS & PM & PH |
| NS & PH & PM & PS & ZE & PS & PM & PH |
| ZE & PH & PM & PS & ZE & PS & PM & PH |
| PS & PH & PM & PS & ZE & PS & PM & PH |
| PM & PH & PM & PS & PS & PS & PM & PH |
| PH & PH & PM & PS & PS & PS & PM & PH |

NH – negative high, NM – negative medium, NS – negative small, ZE – zero, PS – positive small, PM – positive medium, PH – positive high.

**Table 3**

Electrical Engineering & Electromechanics, 2022, no. 1
In this work the fuzzification and defuzzification processes are carried out using asymmetrical triangular membership functions (so that computation complexity can be reduced) as shown in Fig. 7, where each of input variables \( \varepsilon_{\theta_1}, \varepsilon_{\theta_2} \) is mapped into seven different linguistic values. Mapping relationship between the inputs and output variables of FLE is also given in Fig. 8.

![Fig. 7. Fuzzy membership functions of the proposed FLE](image)

![Fig. 8. Control surface of the fuzzy logic estimator](image)

Just like the first step of fuzzification, the defuzzification module transforms the overall control output \( \hat{u} \) obtained in the previous phase, to corresponding physical values (voltage) that system can accept. The voltage vector amplitude is then obtained by multiplying the crisp output value \( d \) by an appropriate gain. This latter is chosen so that the maximum amplitude of the reference voltage vector should not exceed the voltage vector maximum amplitude generated by a two level PWM inverter.

**Principle of Space Vector Modulation strategy.**

SVM technique is an advanced computation intensive PWM method and possibly the best PWM strategy for three-phase VSI used in industrial applications such as control of induction motors. Practically this modulation technique has several advantages either for inverter or motor such as; better utilization of DC-link voltage, less of torque ripples, motor current with lower Total Harmonic Distortion (THD), minimum of switching losses, and simplicity of implementation in digital systems [9, 10, 14, 23].

SVM principle is based on the concept of approximating a rotating reference voltage vector \( \vec{V}_S^* \) by using a combination of two out of the eight possible state vectors that can be generated from a three-phase VSI. This strategy differs from the sinusoidal PWM in such way that, there is no separate modulator used for each of three phases. Instead, the reference voltage vector is processed as a whole. In fact, the SVM is produced by a regular sampling of circular locus reference voltage created on the \( \alpha-\beta \) plane. These voltage samples are then represented by two actives vectors, chosen from \( \vec{V}_1 \) to \( \vec{V}_6 \), that are adjacent to the reference voltage vector together with either two null vectors; \( \vec{V}_0 \) and \( \vec{V}_7 \). The respective times corresponding to these state vectors are adjusted within a sample period [9, 10, 14].

Figure 9 shows the SVM principle, where reference vector \( \vec{V}_S^* \) is sampled at time intervals fixed and equal \( T_s \), called «sub-cycles». The sampled value \( \vec{V}_S(T_s) \) is then used to solve the following equations:

\[
\begin{align*}
T_k &= T_k - T_k + T_{k+1} = T_s - \vec{V}_S(T_s); \\
T_0 &= T_7 = T_s - T_k - T_{k+1},
\end{align*}
\]

(13)

where \( \vec{V}_k \) and \( \vec{V}_{k+1} \) are two switching state vectors adjacent in space, to the reference voltage vector \( \vec{V}_S^* \).

Solution of (13) gives application times of switching state vectors

\[
\begin{align*}
T_k &= \sqrt{3} s \left[ \sin \left( k \frac{\pi}{3} \right) \sqrt{\frac{3}{V_{dc}}} \right] \frac{\bar{V}_S}{V_{dc}}; \\
T_{k+1} &= \sqrt{3} s \left[ -\sin \left( (k-1) \frac{\pi}{3} \right) \sqrt{\frac{3}{V_{dc}}} \right] \frac{\bar{V}_S}{V_{dc}}.
\end{align*}
\]

(14)

If the over-modulation mode \( T_k + T_{k+1} > T_s \) occurs, state vectors application time should be scaled as (15) to generate the best approximation of the reference voltage vector. This may be detected by examining the sign of calculated \( T_0 \) and limit is then applied by maintaining the same angle for the reference voltage vector

\[
\begin{align*}
T_k &= T_k - T_{k+1} = T_s - \bar{V}_S(T_s); \\
T_0 &= T_7 = 0.
\end{align*}
\]

(15)

Having computed these modulation times, an adequate sequence of the state vectors must be well determined. The modulation scheme, used in this work, is based on a symmetrical sequence within each sample period (Fig. 10). Thus, switching sequence applied for a given sector can be described as:

\[
\vec{V}_{0,7} \Rightarrow \vec{V}_k \Rightarrow \vec{V}_{k+1} \Rightarrow \vec{V}_{0,7} \Rightarrow \vec{V}_k \Rightarrow \vec{V}_{0,7}.
\]

This sequence is characterized by the weakest switching losses and also the lowest harmonic distortion due to the resulted symmetry in switching pulses waveform of the inverter power components.

![Fig. 9. Principle of the SVM: a – functional diagram; b – switching state vectors in the first 60°-sector](image)

![Fig. 10. Switching pulses waveform for the first 60°-sector](image)
Modified Direct Torque Control (MDTC). The proposed MDTC structure for IM is shown in Fig. 11, where the hysteresis comparators and switching table of conventional DTC are eliminated and replaced by

- prediction of the reference stator flux;
- determination of the reference voltage space vector;
- application of the SVM technique.

From (16) torque control is directly performed by

\[
\Gamma_e = \frac{3}{2} p L_m^2 \frac{I_m^2}{R_p L_s} \sin^2 \left[ \frac{\Delta \theta_s}{2} \right] \left[ \frac{\Delta \theta_s}{\Delta t} \right].
\]

In order to validate these two approaches of DTC-SVM, their performances are compared, under the same conditions, with those of classical DTC. In turn, the

### Table 4

| Parameters                  | Values          |
|-----------------------------|-----------------|
| Rated power, kW             | 4               |
| Stator voltage, V           | 220             |
| Stator resistance, \( \Omega \) | 1.2             |
| Rotor resistance, \( \Omega \) | 1.8             |
| Stator cyclic inductance, H | 0.1554          |
| Rotor cyclic inductance, H  | 0.1568          |
| Mutual inductance, H        | 0.15            |
| Number of pairs of poles    | 2               |
| Inertia, N·m·rad·s         | 0.07            |
| Friction coefficient, kg·m² | 0.0001          |

**Conclusion.** The effectiveness of the two proposed DTC-SVM structures, the simulation work is carried out, on an IM, using the Matlab/Simulink software and/or fuzzy logic tools. The parameters of used motor are listed in Table 4.
dynamic behaviour of these three DTC structures (with speed IP controller) is tested under high and low speed and with various load torque commands. Simulation results, included in Fig. 13, show that a good tracking performances can still be achieved in the responses of speed, torque, flux and current with no distinct difference among the three DTC approaches (for all tested cases in terms of the damping capability and transient response under different reference speeds and mechanical loads).

For a close inspection of the steady-state performances, we give in Fig. 14, 15 the static responses of the three DTC structures. Where for all, the machine is operating at high speed (100 rad/s) and with full load (20 N·m). From these results, it is possible to see that the two DTC-SVM approaches illustrate some better performances by reducing the ripples in the torque and stator flux and attenuating the speed vibrations.

Fig. 13. System responses for various operating conditions:

- classical DTC;
- DFTC;
- MDTC

Fig. 14. Steady-state responses of stator flux, torque and speed:

- classical DTC;
- DFTC;
- MDTC

For the same steady-state operating conditions, we see significantly in Fig. 15 that the harmonic content of the stator current is quite attenuated by employing mainly the MDTC structure, wherein the stator line voltage is found closer to the desired staircase form.
Moreover, from the trajectories of the stator flux given in Fig. 16, we can notice an appreciable reduction in stator flux ripples, which is obtained with the two DTC-SVM structures. Particularly using the MDTC approach, the stator flux path represents the fastest dynamic response with the lowest ripples.

By representing the inverter switching frequency in Fig. 17, we have demonstrated that the use of SVM strategy in MDTC structure gives in reality a fixed switching frequency and equalling the sample frequency (5 kHz) used in the modulation sequence of stator voltage space vector. On the other hand, we have verified that with DFTC structure the switching frequency has a fixed average value for various speed or torque references.

Therefore, from this analysis we have shown that the two proposed structures of DTC-SVM exhibit good static and dynamic performances with low torque ripples and a fixed switching frequency (over a wide range of torque or speed control). All of these benefits are obtained through the use of the SVM strategy and the speed IP controller.

\[a\] – classical DTC; \[b\] – DFTC; \[c\] – MDTC

Conclusions.
The study of the two proposed direct torque control approaches (with space vector modulation), applied to the induction motor drive, is carried out here by means of physical considerations, analytical developments and simulation tests. Thus demonstrating how the electromagnetic torque and the stator flux can be kept under control through the application of the space vector modulation strategy.

A comparison between the classical direct torque control and the two direct torque control structures (with space vector modulation) is presented where the modification aim was some drawbacks attenuation of conventional direct torque control such as; the torque ripples, current distortion and random switching frequency variation. Indeed, the two proposed direct torque control approaches (with speed IP controller) have shown, through the different simulation tests, their effectiveness and superiority over the classical direct torque control without deteriorating the dynamic control capability of this technique.

The foremost revealed improvements of these two approaches are:
- ripples reduction in the torque and stator flux for either static or dynamic responses (under high and low speed operation);
- more attenuated distortion in the stator voltage and current waveforms by using the modified direct torque control structure;
- a switching frequency with fixed average value is achieved under various operating conditions (thanks to use of the space vector modulation strategy);
- fast dynamic response for the stator flux and a constant switching frequency in the inverter by using particularly the modified direct torque control structure.
In fact, the lowest switching frequency is obtained with the modified direct torque control approach. That will reduce the switching losses as well as stress on the inverter semiconductor components. Also, the modified direct torque control structure is more suitable for real time implementation due to its efficiency and simplicity.
