Changes in Body Mass Index and its Relationships to Other Cardiovascular Risk Factors among Japanese Population: Results from the 1980 and 1990 National Cardiovascular Surveys in Japan

Longjian Liu, Sohel R Choudhury, Akira Okayama, Takehito Hayakawa, Yoshikuni Kita, and Hirotugu Ueshima

Few studies have attempted to investigate the changes in body mass index (BMI) and its relationship to other cardiovascular factors in Asian populations, including Japanese. Data from two national cross-sectional surveys on circulatory disorders in 1980 and 1990 in Japan were used in this study. The sample consisted of 10,556 participants in the 1980 survey and 8,385 in the 1990 survey, aged ≥30 years. The results show that after adjusting for age, smoking, alcohol consumption (ALC) and daily life physical activity (PA), mean BMI increased 0.49 kg/m² (95% confidence interval: 0.34-0.65) in men aged 30-59 and 0.61 kg/m² (0.37-0.86) in those aged ≥60 from 1980 to 1990. In women, however, mean BMI decreased 0.24 kg/m² (-0.39 0.09) in those aged 30-59 and increased 0.38 kg/m² (0.12-0.64) in those aged ≥60. BMI was significantly associated with hypertension, diabetes and hypercholesterolaemia. In both genders, cu-smokers had lower mean BMI than never smokers, while among the cu-smokers, mean BMI was positively associated with the number of cigarettes smoked per day. In men, BMI was positively associated with ALC and negatively associated with PA, while in women, BMI was negatively associated with ALC and positively associated with PA. The results suggest that BMI has significantly increased in men and in elderly women. BMI, even in the Japanese population who are characterized by relative low BMI, is significantly associated with several cardiovascular risk factors. J Epidemiol, 1999; 9: 163-174

In Japan, malignant neoplasm and cardiovascular disease are major causes of death. Among the major causes of death, age-adjusted mortality rates from both cerebrovascular disease and heart disease, including coronary heart disease (CHD), have been declining since 1970. These changes have been thought to result primarily from the control of high blood pressure, including both primary and secondary preventive measures. However, since the intake of fat has increased with lifestyle westernization, there is some concern that both mortality and morbidity from CHD may soon show an increasing trend. If potentially epidemic CHD is to be prevented, it is important to understand the trends in cardiovascular risk factors. Some previous studies have reported an increase in serum cholesterol concentrations and an increase in the prevalence of diabetes mellitus in Japan. However, little attention has been paid to changes in the body mass index (weight (kg)/height(m²)). Furthermore, possibly because Asian populations, including Japanese, have a much lower body mass index (BMI) than Caucasians, the associations between BMI and other cardiovascular factors are not well understood in Asian populations. In the present study, we used data of the 1980 and 1990 National Cardiovascular Surveys in Japan to investigate the changes in BMI, and the associations between BMI and the prevalence of hypertension, diabetes mellitus, hypercholesterolaemia, cigarette smoking, alcohol consumption and daily life physical activity.

METHODS

Design of the surveys

The Ministry of Health and Welfare of Japan organized the 1980 and 1990 National Cardiovascular Surveys. The two surveys had a similar study design, but were independently carried out. For the 1980 survey, 300 districts were randomly selected from the "Survey of Sample Districts of Population for Statistics of Health and Welfare" 6. The subjects were all residents aged 30 or older by the 1st of November 1980. The total number of eligible residents was 13,771. However, 10,897 persons were actually examined in the survey. Consequently, the overall participation rate was 79.1% (73.8% for men and 84.3% for women). In the 1990 survey, 300 districts were drawn at random from the 1990 National Livelihood Survey of households and household members in all parts of Japan 7. The total number of eligible residents using the same age criterion as in the 1980 survey was 10,956. However, only 8,926 individuals were actually examined, for a participation rate of 81.5%: 76.1% for men and 86% for women. In the present study, subjects who had completed physical examinations, blood tests and questionnaire surveys were included in the data analyses. Overall, the sample size was 10,556 in 1980 and 8,385 in 1990.

The methods used for the examinations were described in detail in the reports on the two surveys 6,7. Briefly, height (cm) and weight (kg) were measured in bare feet and in light clothing. Blood pressure was measured in mmHg in each participant's right arm, with a standard mercury sphygmomanometer. Urinary glucose was tested by paper colorimetry, and the results were classified as negative or positive. Total cholesterol was measured by an enzymatic method with a Hitachi 736-60. For both the 1980 and 1990 surveys, cooperation was obtained from the Department of Epidemiology and Mass Examination for Cardiovascular Diseases, Osaka Medical Center for Cancer and Cardiovascular Diseases, which has 16 years of experience with the U.S. CDC-NHLBI Lipid Standardization Program of the Centers for Disease Control 6,7.

Statistical methods

BMI was calculated as weight(kg)/height(m^2) and was used as a continuous variable in the data analysis. It was also categorized into four levels according to quartiles of the BMI distributions of subjects in the 1980 and 1990 surveys. Overweight was classified as BMI ≥ 25 kg/m^2.

Hypertensive subjects were those who had systolic blood pressure ≥ 160 mmHg or diastolic blood pressure ≥ 95 mmHg, or who were under treatment with antihypertensive agents. In both 1980 and 1990 surveys, although blood glucose levels were determined, however, methods of their measurements were different, and glycohemoglobin Alc was tested only in the 1990 survey. Therefore, in the present study, subjects were classified as diabetes mellitus (DM) for any of the following conditions: self-reported history of DM or positive urinary glucose test because only these were available and comparable as crude indices of DM in the 1980 and 1990 surveys 6,8. Hypercholesterolaemia was defined as total cholesterol ≥ 220 mg/dl.

Cigarette smoking status was classified as never smoking, ex-smoking or cu-smoking (current smoking). Cu-smokers were further divided into those who smoked 1-20, 21-40 and ≥ 41 cigarettes per day. According to the available data on drinking habits in the 1980 and 1990 surveys, alcohol consumption was divided into three categories: never, ex- and cu-drinking. Daily life physical activity was classified into three categories that are usually used in Japan. This classification is based on both occupational and leisure time physical activity. The category I is the least active group, and the category III is the most. The category I (light) usually includes sedentary workers and housewives without infants and toddlers. The category II (moderate) includes industry workers and self-employed women. The category III (heavy) includes farmers, fishermen and professorial sportsmen.

To test differences in mean BMI and the prevalence of overweight between the 1980 and 1990 surveys, t-tests and Chi-square tests were used by gender and by five 10-year age groups (30-39, 40-49, 50-59, 60-69 and 70 years or over). The changes in BMI, by gender and age (30-59 and 60 or over), were further examined by adjusting for age and three lifestyle factors (smoking, alcohol consumption and daily life physical activity) using analyses of covariance method. To examine the associations between BMI and hypertension, DM and hypercholesterolaemia, logistic regression models were used to calculate multi-adjusted odds ratios (OR) and the 95% confidence interval (95%CI) of OR. In these models, hypertension, diabetes or hypercholesterolaemia was the dependent variable (binary, 0=no, 1=yes), and BMI was the independent variable (by quartiles). The multi-adjusted factors were age, smoking, alcohol consumption and daily life physical activity. To explore the relationships between BMI and three lifestyle factors (smoking, alcohol consumption and daily life physical activity), age-adjusted mean BMI was compared between three categories of each factor by gender and survey year. Finally, the 1980 and 1990 surveys were combined and further analyzed using two multiple linear regression models. In these linear regression models, BMI was the dependent variable (continuous) and lifestyle factors were the independent variables by adjusting for survey year and age. Model 1 included all of the subjects in the total combined sample, while model 2 included subjects who were cu-smokers. In model 1, survey year was coded as 0 for the 1980 survey and 10 for the 1990 survey, age was used as a continuous variable (years), ex-smoking and cu-smoking were coded as two dummy variables (0=no, 1=yes), drinking habits were coded as: 0= never drinking, 1=ex-drink-

a) Daily life physical activity was classified based on subject's occupational and leisure time physical activity.

b) Subjects were classified as having hypertension for those who had SBP ≥ 160 or DBP ≥ 95 mmHg, or who were under treatment with antihypertensive agents.

c) Subjects were classified as diabetes mellitus (DM) for any of the following conditions: self-reported history of DM or positive urinary glucose.

d) Hypercholesterolaemia was defined as total cholesterol ≥ 220 mg/dl.
ing and 2=cu-drinking, and daily life physical activity was coded as: 0=light, 1=moderate and 2=heavy. In model 2, the same coding values for adjusted and independent variables were used as in model 1, except that smoking status was coded according to the number of cigarettes smoked daily (1, 2 and 3 for subjects who smoked 1-20, 21-40 and ≥41 cigarettes per day). SPSS ver. 7.5 software was used for all data analyses.

**RESULTS**

**General characteristics of the two surveys**

Table 1 shows the general characteristics of the 1980 and 1990 surveys. Both men and women were older in the 1990 survey than in 1980 (mean age 53 vs. 50 years for both genders). Mean BMI in men was higher in 1990 than in 1980 (22.96 vs. 22.5 kg/m²), but appeared to be similar in women between the two surveys (22.84 vs. 22.83 kg/m²). The mean systolic blood pressure (SBP) and diastolic blood pressure (DBP) were similar in the 1980 and 1990 surveys in both genders. Mean total cholesterol was higher in 1990 than in 1980 in both genders. The prevalence of cu-smoking and cu-drinking were lower in 1990 than in 1980 in men and women. The percentage of subjects who engaged in light physical activity was higher in 1990 than in 1980 in men and women. The prevalence of hypertension was similar between 1980 and 1990 in men, but was higher in 1990 in women. The prevalence of DM and hypercholesterolaemia were higher in 1990 than in 1980 in men and women.

**Changes in body mass index and prevalence of overweight by gender and age**

Table 2 shows that, among men, mean BMI and the prevalence of overweight significantly increased from 1980 to 1990 in the five 10-year age groups. Mean BMI increased between 0.37 and 0.67 kg/m², and the prevalence of overweight increased from 4.4 to 6.1 percentage points. In women aged <50 years, mean BMI significantly decreased from 0.32 to 0.39 kg/m², while mean BMI in those aged 60-69 significantly increased 0.49 kg/m² from 1980 to 1990. Increased BMI was also observed in women aged 50-59 and in those aged ≥70

years, but these differences between the 1980 and 1990 sur-
veys were not significant. The prevalence of overweight
decreased in women under 60 years, but increased in those
aged ≥ 60 years from 1980 to 1990. Taking into considera-
tion of birth-cohort effects on BMI, for example, the comparis-
on of BMI between subjects aged 30-39 years in 1980 and those
aged 40-49 years in 1990 (a 10-years aging effect), Table 2
also shows that, even in women, aging is found to be associat-
ed with increasing BMI among the population under 70 years
old.

Table 3 shows that after adjusting for age, smoking, alcohol
consumption and daily life physical activity, mean BMI (95% CI) significantly increased 0.49 kg/m² (0.34 - 0.65 kg/m²) in
men aged 30-59, and 0.61 kg/m² (0.37 - 0.86 kg/m²) in those
aged ≥ 60 from 1980 to 1990. In women, however, mean BMI
significantly decreased 0.24 kg/m² (-0.39 - 0.09 kg/m²) in sub-
jects aged 30-59 and increased 0.38 kg/m² (0.12 - 0.64 kg/m²)
in those aged ≥ 60 from 1980 to 1990.

Table 4 shows that among men and women, age-adjusted
prevalence of hypertension decreased, while the prevalence of
diabetes and hypercholesterolaemia increased among both
younger (30-59 years) and older (≥60 years) subjects from
1980 to 1990.

a) Definition for hypertension, diabetes mellitus and hypercholesterolaemia, see Table 1 notes.
b) Age-adjustment by using the 1985 Standard Population of Japan.

**Body mass index and risk of hypertension, diabetes and hypercholesterolaemia**

The associations between BMI (by quartiles) and risk of hypertension, diabetes and hypercholesterolaemia are presented in Table 5 according to two age groups (30-59 and ≥ 60 years). In general, increased BMI was consistently and significantly associated with an increasing risk of hypertension, diabetes and hypercholesterolaemia in both genders in the 1980 and 1990 surveys, with the exception of the multi-adjusted odds ratios for the risk of diabetes in men and women aged 30-59 in 1990, which appeared to be inversely associated with BMI. However, these latter odds ratios were not significant.

**Body mass index and lifestyle factors**

Table 6 shows that among men, cu-smokers had lower BMI compared with never smokers and ex-smokers. Among cu-smokers, however, an increase in the number of cigarettes smoked daily was associated with increased mean BMI, and these associations were significant in those aged 30-59 years in the 1980 and 1990 surveys. Ex-smokers appeared to have slightly lower BMI than never smokers in the 1980 survey, and a slightly higher BMI in the 1990 survey. Drinkers (ex- and cu-drinking) appeared to have higher mean BMI than never drinkers in 1980 and 1990 surveys, but these differences were not significant. Subjects with light physical activity had the highest age-adjusted mean BMI in the 1980 and 1990 surveys, except that those aged 30-59 years old in the 1980 survey had a slightly lower mean BMI than those with heavy physical activity.

In women aged ≥ 60 years in the 1980 survey, cu-smokers had significantly lower age-adjusted mean BMI than ex-smokers and never smokers. Among cu-smokers, an increase in the number of cigarettes smoked daily was significantly associated with increasing mean BMI in those aged 30-59 years, while the association was not clear in those aged ≥ 60 in the 1980 and 1990 surveys. There was no clear association between drinking and BMI in women, although cu-drinkers had a lower BMI than never drinkers. Women whose physical activity was categorized as "light" appeared to have lower age-adjusted mean BMI than those with moderate and heavy physical activities in both the 1980 and 1990 surveys, with the exception of those aged ≥ 60 in the 1990 survey.

Table 7 shows the results of the associations between BMI and lifestyle factors by combining the 1980 and 1990 surveys. Prior to this analysis, these associations were initially analyzed for the 1980 and 1990 surveys separately (by adjusting for age and lifestyle factors), and then for the combined sample of the two surveys (by adjusting for survey year, age and lifestyle factors). The separate results for the 1980 and 1990 surveys were not shown because they were similar to the results of the combined sample. Model 1 indicated that among all of the subjects, BMI was negatively and significantly associated with cu-
Table 5. Multi-adjusted odds ratios (95% CI) for body mass index (by quartiles) associated with the prevalence of hypertension, diabetes mellitus and hypercholesterolaemia by two age groups in 1980 to 1990 for men and women a,b,c).

a) Subjects were classified as having hypertension for those who had SBP ≥ 160 or DBP ≥ 95 mmHg, or who were under treatment with antihypertensive agents. Subjects were classified as diabetes mellitus (DM) for any of the following conditions: self-reported history of DM or positive urinary glucose test. Hypercholesterolaemia was defined as total cholesterol ≥ 220 mg/dl.
b) BMI-Q1, BMI-2, BMI-3 and BMI-4 are for quartiles of body mass index 1 (less than 20.52 kg/m²), 2 (20.52-22.51 kg/m²), 3 (22.52-24.68 kg/m²) and 4 (24.69 kg/m² or more). Odds ratios were calculated in comparison to quartile 1.
c) Multi-adjusted factors: age (year), smoking (0=never smoking, 1=ex-smoking and 2=cu-smoking), drinking (0=never drinking, 1=ex-drinking, 2= cu-drinking) and daily life physical activity (0=light, 1=moderate and 2=heavy).

Among cu-smokers, the associations between BMI and lifestyle factors were examined by model 2. A significant positive association between BMI and the number of cigarettes smoked daily was observed in both genders aged 30-59 years. Among male cu-smokers, alcohol consumption was positively, and physical activity was negatively, associated with BMI, but these associations were not significant. In female cu-smokers, BMI was negatively and significantly associated with alcohol consumption in those aged 30-59 years, while there was no significant association between BMI and physical activity.

**DISCUSSION**

Our study has three important features: (1) the results are based on the most recent representative nationwide surveys in Japan, (2) it is the first detailed study to focus on the changes in BMI and the relationships between BMI and other cardiovascular factors in Japanese, and (3) the results may be informative for other Asian countries, since with their economic development and possible lifestyle westernization, they may experience the same changes in cardiovascular factors as Japan.
Table 6. Age-adjusted mean body mass index (kg/m²) and lifestyle factors by two age groups in 1980 and 1990 for men and women.

| Smoking status       | 1980 Aged 30-59 | 1980 Aged ≥ 60 | 1990 Aged 30-59 | 1990 Aged ≥ 60 |

Changes in body mass index

Our findings indicate that BMI significantly increased in Japanese men aged ≥ 30 and in women aged ≥ 60 years. In contrast, BMI significantly decreased in women aged 30-59. These associations were independent of age, smoking, alcohol consumption and daily physical activity. Similar to the results in BMI, the prevalence of overweight increased in men in each 10-year age-group. In women, however, the prevalence of overweight decreased in those under 60 years, and increased in those over 60 years old.

Among men, increases in BMI and the prevalence of overweight have been reported in several Western countries. Among middle-aged women, increases in BMI and the prevalence of overweight have also been recently seen in the United Kingdom, the United States, Sweden and Australia, but not in Italy, Finland or The Netherlands. There are comparatively few studies in Asian countries. In China, Ge et al., using China Nutrition Surveys, reported that mean BMI increased from 1980 to 1989 in Chinese men and women, and the proportion of obesity (BMI > 25 kg/m^2) increased 4.8% for urban residents and 2% for rural residents aged 20-45 years. In Japan, the trend in BMI from 1956 to 1980 was reported by Ueshima et al. In a recent report by Sakata et al., the changes of BMI from 1970 to 1990 were described, while other potential confounding factors were not considered in their data analyses, such as smoking, alcohol consumption and daily life physical activity. Thus, our study has extended previous studies and provides more detailed information on the changes in BMI. The increase in BMI and the prevalence of overweight in Japanese men aged ≥ 30 and women aged ≥ 60 years may be due to changes in several factors such as dietary, social and demographic, and behavioural factors. Our study suggests that smoking, alcohol consumption and daily life physical activity had only a small effect on mean level of BMI. Changes in diet may have the strongest effect. The Japan National Nutrition Surveys in 1980 and 1989 indicated that the percentage of calories supply from fat increased from 22.6% to 25.7%, while that from cereals decreased from 48% to 45.1%. Fish and bean consumption has changed little, while meat, milk and milk product consumption has gradually increased in
Japanese from 1980 to 1989. The reason for the decrease in BMI among young women is not clear. It is possible that young Japanese women may have prevented overweight by paying attention to their diet over the past 10 years. However, among both genders who were aged less than 70 years, the associations between aging and increased BMI (birth-cohort effect) suggest that both effects of aging and changes in lifestyles on BMI should be considered in public health programme for control of body weight.

The present study also shows a decrease in prevalence of hypertension, and increases in prevalence of diabetes and hypercholesterolaemia from 1980 to 1990 (Table 4). Several studies have confirmed that the decrease in prevalence of hypertension is mainly because of improvements in the control of high blood pressure in both lifestyle changes (such as decrease in salt intake), and medical treatment. However, the increases in prevalence of diabetes and hypercholesterolaemia are strongly suggested to be associated with changes in dietary habits (such as increase in fat intake), and increase in body weight over the past 10 years.

**Body mass index and risk of hypertension, DM and hypercholesterolaemia**

Hypertension, DM and hypercholesterolaemia are well-established risk factors for coronary heart disease. A local study in Kyushu, Japan, reported that increased BMI was significantly associated with a high risk of diabetes. In our study, we confirmed that increased BMI was significantly associated with the risk of hypertension, DM and hypercholesterolaemia in both men and women. The association between BMI and DM showed some complicated or inverse associations in those aged 30-59 the 1990 survey (Table 5), while these results may be due to chance (P>0.05). In our present study, a possible limitation was that the definition of DM was based on the subject's self-reported medical history and the results of a urinary glucose test. There were no further examinations to confirm disease status. Therefore, misclassification or underestimation of the prevalence of DM might have occurred.

**Body mass index and lifestyle factors**

Smokers tend to weigh less and have a lower BMI than never smokers, and people who stop smoking tend to gain weight and have an increased BMI. Some studies have also indicated that among smokers, BMI is positively associated with an increase in the number of cigarettes smoked. The results in our study are consistent with these previous results. The mechanism of the association between BMI and smoking is not completely understood. One explanation is that smoking reduces the appetite. Among smokers, however, heavy smoking may be part of a cluster of substance-abuse behaviours, including over-eating and alcohol consumption.

Previous reports on the associations between BMI and alcohol consumption are inconsistent. For example, the association between BMI and alcohol consumption was significantly associated with a high relative weight in men, whereas no such relation was found in women. Tavani et al. found no significant differences in age-adjusted mean BMI between drinkers and nondrinkers. Our study shows a positive relationship between BMI and alcohol consumption in men. One reason may be that most Japanese male drinkers are moderate or heavy drinkers, and they often eat more fatty food than never drinkers and light drinkers. Among women, however, a significant negative association between BMI and drinking was observed in cu-smokers aged 30-59 years. One of the explanations is that most Japanese female drinkers have light drinking habits. It should be noted that, in the present study, categories of drinking habits in 1980 and 1990 surveys were not well comparable (Table 1) due to the different definitions in their questionnaires. In the 1990 survey, prevalence of cu-drinkers may have been under-estimated for both men and women, and some of cu-drinkers (especially, light drinkers) may have been classified as never drinkers. This limitation may lead to under- or over-estimate the associations between alcohol consumption and BMI, and other factors. To keep this in mind, the present results may provide some evidence for further studies.

An inverse association between daily life physical activity and BMI in men and women has been supported by some studies. In our study, after adjusting for survey year, age, smoking and alcohol consumption, this inverse association was seen in men. In women, however, BMI was positively associated with daily life physical activity, and this association was significant in those aged 30-59 years. It should be noted that in the present study, physical activity was generally classified according to the subject's occupational and leisure time physical activity, because detailed information on physical activity was not available from the 1980 and 1990 surveys. Therefore, from the study, we can not make a conclusion regarding this association between BMI and physical activity in Japanese.

In conclusion, despite of some limitations, using the most recent large Japanese surveys, our results show that both BMI and the prevalence of overweight increased in men aged ≥ 30 and in women aged ≥ 60 years. In young adult women, however, mean BMI and the prevalence of overweight have decreased. Further studies are required to examine the possible determinants. Our findings also suggest that even in the Japanese population who are characterized by relative low BMI, and with a low incidence and mortality from coronary heart disease, BMI is significantly associated with several established risk factors of coronary heart disease, such as hypertension, diabetes, hypercholesterolaemia and heavy smoking.
ACKNOWLEDGMENTS

The study was supported by a Research Grant for Cardiovascular Disease (7C-2) from the Ministry of Health and Welfare of Japan. Dr. Longjian Liu, from Department of Epidemiology, Chongqing University of Medical Science, China, was awarded a fellowship (L97559) from the Japan Society for the Promotion of Science for his study in the Department of Health Science, Shiga University of Medical Science, Otsu, Japan.
