Abstract

**Background:** Osteoarthritis (OA) may increase urinary tract infection (UTI) in older adults. However, this issue remains unclear.

**Methods:** We identified 8599 older patients (≥65 years) with OA, and an equal number of older patients without OA, matched by age, sex, and index date from the Taiwan National Health Insurance Research Database between 2001 and 2005. Past histories, including UTI and underlying comorbidities, were included in the analyses. Comparisons for any UTI, ≥1 hospitalization for UTI, and ≥3 hospitalizations for UTI between the two cohorts by following up until 2015 were performed.

**Results:** In both cohorts, the percentages of age subgroups were 65–74 years (65.7%), 75–84 years (30.1%), and ≥85 years (4.2%). The male sex was 42.4%. Patients with OA had an increased risk of any UTI compared with those without OA after adjusting for all past histories (adjusted hazard ratio [AHR]: 1.72; 95% confidence interval [CI]: 1.64–1.80). The Kaplan–Meier curve and log-rank test showed that OA increased any UTI (p < .001). Compared with patients without OA, patients with OA also had an increased risk of ≥1 hospitalization for UTI and ≥3 hospitalizations for UTI (AHR: 1.13; 95% CI: 1.06–1.19 and AHR: 1.25; 95% CI: 1.13–1.38, respectively). In addition to OA, older age, female sex, history of UTI, benign prostatic hyperplasia, indwelling urinary catheter, cerebrovascular disease, diabetes, dementia, and urolithiasis were independent predictors for any UTI.

**Conclusions:** OA increased UTI in older adults. We suggest appropriately managing OA and controlling underlying comorbidities to prevent subsequent UTI.

1. Introduction

The aging population is an important worldwide issue. In the United States, the older population (≥65 years) is projected to grow from 49 million to 95 million between 2020 and 2060[1]. In Taiwan, older adults were 14% of the total population in 2018, and are projected to be 20% in 2025[2]. The percentage of very old adults (≥85 years) in the older population will increase from 10.3–27.4% between 2020 and 2070[2]. Urinary tract infections (UTIs) are responsible for 15.5% of hospitalizations and 6.2% of deaths attributable to infectious diseases in older adults[3]. In institutionalized adults, UTIs are the most common infections[4, 5]. Recurrent UTIs in older adults increases morbidity, mortality, and personal and social burdens[6].

Osteoarthritis (OA) is the most common joint disease and one of the most frequent causes of pain and disability[7]. OA was found in many older adults, and nearly 80% of older people aged over 75 years[7]. In the United States, OA is the second cause of work disability in men over 50 years of age[7]. OA of the knee and hip can affect walking, climbing stairs, and self-care, and eventually result in decreased quality of life[8, 9]. Because of pain and decreased physical activity, OA is associated with higher healthcare usage and increased risks of obesity, depression, cardiovascular disease, renal disease, and diabetes[10]. A previous study reported that decreased physical activity might increase UTI[11]. However, we did not
find any study about the association between OA and UTI in older adults by searching using the keywords “older adult,” “osteoarthritis,” and “urinary tract infection” in PubMed and Google Scholar. Therefore, we conducted the present study to investigate this issue. We hypothesized that UTI might increase in older adults with OA.

2. Methods

2.1 Data source

This nationwide population-based cohort study was conducted using the Longitudinal Health Insurance Database 2000 (LHID 2000), which is a data subset from Taiwan's National Health Insurance Research Database (NHIRD)[12]. The National Health Insurance system of Taiwan covers more than 99.6% of the Taiwanese population, and the claims data of this system are released as the NHIRD[12, 13]. The LHID 2000 contains 2,000,000 individuals randomly sampled from the NHIRD using random number generators[12]. The distribution of age and sex are not different between patients in the LHID 2000 and those in the NHIRD[12].

2.2 Study design, setting, and participants

We identified older patients (≥ 65 years) with OA between 2001 and 2005 as the study cohort and an equal number of older patients without OA by matching age, sex, and index date as the comparison cohort. The diagnosis of OA was defined when the patient had the diagnosis of International Classification of Diseases, Ninth Revision, Clinical Modification (ICD-9-CM) of 715 or 721, and at least one hospitalization or three outpatient clinic visits. Underlying comorbidities and potential risk factors for UTI[14, 15], including a history of UTI, benign prostatic hyperplasia (BPH), an indwelling urinary catheter, cerebrovascular disease, diabetes, dementia, and urolithiasis were included in the analyses.

2.3 Definitions of variables

The age subgroups were classified as 65–74 years, 75–84 years, and ≥ 85 years[16–19]. We defined the underlying comorbidities as follows: a history of UTI (ICD-9-CM 590, 595, 597, 599.0, 601), BPH (ICD-9-CM 600), indwelling urinary catheter (ICD-9-CM Vol. 3 Procedure Codes 57.94), cerebrovascular disease (ICD-9-CM 430–438), diabetes (ICD-9-CM 250), dementia (ICD-9-CM 290, 294.1, 294.2, 331), and urolithiasis (ICD-9-CM 592, 594). We further divided OA into four subtypes: the upper limbs (ICD-9-CM 715.04, 715.11, 715.12, 715.13, 715.14, 715.21, 715.22, 715.23, 715.24, 715.31, 715.32, 715.33, 715.34, 715.91, 715.92, 715.93, 715.94), lower limbs (ICD-9-CM 715.15, 715.16, 715.17, 715.25, 715.26, 715.27, 715.35, 715.36, 715.37, 715.95, 715.96, 715.97), spine (ICD-9-CM 721.0, 721.1, 721.2, 721.3, 721.41, 721.42, 721.5, 721.6, 721.7, 721.8, 721.90, 721.91), and others (ICD-9-CM 715.00, 715.09, 715.10, 715.18, 715.20, 715.28, 715.30, 715.38, 715.80, 715.89, 715.90, 715.98). Patients who have been diagnosed with the above-listed diseases, hospitalized at least once, or had three outpatient clinic visits were defined as having the diseases.

2.4 Outcome measurements
We compared the risks of any UTI (≥ 1 outpatient clinic visit, emergency department visit, or hospitalization for UTI), ≥ 1 hospitalization for UTI, and ≥ 3 hospitalizations for UTI between the two cohorts through follow-up until 2015.

2.5 Ethical statements

This study was conducted in accordance with the Declaration of Helsinki and was approved by the Institutional Review Board at Chi Mei Medical Center. Although informed consent was waived while using NHIRD data, all datasets are anonymized to protect individuals’ confidentiality. Personal identity, birth date, and names are encrypted, and this de-identification process was approved by an independent third-party organization[20]. The waiver does not affect the rights and welfare of the participants.

2.6 Statistical analysis

We used SAS 9.4 for Windows (SAS Institute, Cary, NC, USA) for all statistical analyses. Pearson chi-square tests were used for categorical variables. We used a competing risk survival analysis to compare the risks of any UTI, ≥ 1 hospitalization for UTI, and ≥3 hospitalizations for UTI between the two cohorts. Cox proportional hazard regression analyses were used to investigate any UTI’s independent predictors in all older patients. A Kaplan–Meier curve and log-rank test were used for comparing any UTI between the two cohorts during the follow-up period. We set the significance level at $p < .05$ (two-tailed).

3. Results

A total of 8599 patients with OA and 8599 patients without OA were identified for the present study (Table 1). In both cohorts, individuals aged 65–74 years comprised the largest age subgroup (65.7%), followed by 75–84 years (30.1%), and ≥85 years (4.2%). The male percentage was 42.4%. Compared with patients without OA, patients with OA had a higher prevalence of past histories of UTI, BPH, an indwelling urinary catheter, cerebrovascular disease, and urolithiasis, but a lower prevalence of dementia. There was no significant difference in diabetes between the two cohorts.

Patients with OA had an increased risk of any UTI than those without OA after adjusting for a history of UTI, BPH, an indwelling urinary catheter, cerebrovascular disease, diabetes, dementia, and urolithiasis (adjusted hazard ratio [AHR]: 1.72; 95% confidence interval [CI]: 1.64–1.80) (Table 2). The increased risk was also found in the stratified analyses, including age subgroups, sex, past histories of UTI, BPH, indwelling urinary catheter, cerebrovascular disease, and diabetes. The increased risk of any UTI was most prominent in the age subgroup of ≥85 years (AHR: 2.59; 95% CI: 2.00–3.36). The Kaplan–Meier curve and the log-rank test also revealed an increased risk of any UTI in patients with OA than those without OA (Figure 1).
In the comparison of ≥1 hospitalization for UTI and ≥3 hospitalizations for UTI, patients with OA had an increased risk than those without OA (AHR: 1.13; 95% CI: 1.06–1.19 and AHR: 1.25; 95% CI: 1.13–1.38, respectively) (Table 3 and Table 4). In the age subgroup of 65–74, the differences in risk of ≥1 hospitalization for UTI and ≥3 hospitalizations for UTI were not significant between the two cohorts. Compared with other age subgroups, aged ≥85 years had the most prominent risk of ≥1 hospitalization for UTI (AHR: 1.62; 95% CI: 1.25–2.10) and ≥3 hospitalizations for UTI (AHR: 2.37; 95% CI: 1.47–3.82).

In addition to OA, other independent predictors for any UTI in all older patients were older age (AHR: 1.32; 95% CI: 1.27–1.39 in 75–84 years and AHR: 1.52; 95% CI: 1.36–1.70 in ≥85 years), female sex (AHR: 1.47; 95% CI: 1.41–1.54), a past history of UTI (AHR: 2.95; 95% CI: 2.67–3.26), BPH (AHR: 1.43; 95% CI: 1.31–1.57), an indwelling urinary catheter (AHR: 1.30; 95% CI: 1.23–1.38), cerebrovascular disease (AHR: 1.39; 95% CI: 1.29–1.49), diabetes (AHR: 1.34; 95% CI: 1.27–1.42), dementia (AHR: 1.44; 95% CI: 1.23–1.68), and urolithiasis (AHR: 1.29; 95% CI: 1.06–1.57) (Table 5). Compared with patients without OA, patients with subtypes of OA, including the upper limbs, lower limbs, spine, other areas, also had an increased risk of any UTI.

4. Discussion

The present study showed that OA, including its subtypes, was associated with an increased risk of subsequent UTI in older patients. The impact of OA on subsequent UTI was most prominent in the age subgroup of ≥85 years. In addition to OA, older age, female sex, a history of UTI, an indwelling urinary catheter, cerebrovascular disease, diabetes, dementia, and urolithiasis were also independent predictors for any UTI.

A possible explanation for UTI’s increased risk is that patients with OA have decreased physical activity and even immobilization due to pain. This reduced activity predisposes them to inferior body function, sarcopenia and frailty, diabetes, and immune deficiencies related to UTI[10, 15, 21-23]. A study by Rosemann et al. reported that patients with OA of the lower limb had decreased physical activity than those without OA[21]. Another study by Hirata et al. found that more than 40% of women with hip OA were physically inactive and lacked moderate-intensity activity[24]. A national study by Zhu et al. reported that a greater number of bedridden days was an independent risk factor for UTI[25]. A study by Shang et al. about patients in home health care reported that limited physical function status was a risk factor for infections, including UTI[26]. In contrast to decreased physical activity, a large cohort study by Roger at al. reported that avoiding immobilization and an ability to walk were associated with a 69% lower hospitalization rate for UTI in older adults admitted to a skilled nursing facility[15]. Even in residents with severe mobility problems, including being in a wheelchair or having a missing limb, maintaining or improving mobility (in bed or when transferring) could reduce the risk of hospitalization for UTI by 38% to 80%[15].

A decrease in physical activity may cause the inability to urinate frequently, urinary retention, and urolithiasis, and then increase UTI risk[15, 25]. Decreased physical activity may decrease the abdominal
organs’ pressure on the urinary bladder and decrease the urge to urinate, even when the bladder is full[27]. The bone will turnover to create hypercalciuria, and urine will collect in the lower portions of the renal calyces when the body is immobilized or in the supine position, which increases the risk of renal calculi formation even further[28]. Physical inactivity is also a major contributing factor for sarcopenia, frailty, and adverse outcomes[22, 29]. Sarcopenia and frailty are also associated with impaired bladder function, which may increase UTI risk[30]. Therefore, the impact of OA is broad. Also, many adverse outcomes associated with OA affect each other and result in a vicious circle.

The increased risk of UTI was more prominent in the age subgroup of ≥85 years and suggested that this older population is more sensitive to the effects of OA on developing subsequent UTI. In addition to OA, the present study found that older age, female sex, a history of UTI, an indwelling urinary catheter, cerebrovascular disease, diabetes, dementia, and urolithiasis were also independent predictors of UTI, which is compatible with previous studies[14, 15]. All subtypes of OA, including the upper limbs, lower limbs, spine, and other areas, were associated with increased UTI risk. There was no study about comparing subtypes of OA and subsequent UTI. The results suggest that the influence of pain and decreased physical activity are specific to older adults, regardless of OA type.

The present study’s major strengths are its nationwide design, large sample size, and the clarification of an uncertain issue. The limitations are as follows. First, detailed information related to UTI, including activities of daily living, was not available in the NHIRD, which may confound the present results. However, we had matched age, sex, and adjusted the potential risk factors for UTI. Thus, we believe that the confounding effect is minimal. Second, although we found an association between OA and UTI, the causal relationship between OA and UTI could not be entirely clarified because there is a complex interaction among OA, UTI, and other comorbidities. Third, the present result may not be generalized to other nations because of the differences in race, culture, and medical insurance, and, therefore, further studies in other nations are warranted.

5. Conclusions

This nationwide population-based cohort study showed that UTI’s risk increased in older patients with OA, especially in the age subgroup of ≥85 years old. Decreased physical activity in older patients with OA may be the major contributing factor. In addition to OA, other independent predictors for UTI were older age, female sex, a history of UTI, an indwelling urinary catheter, cerebrovascular disease, diabetes, dementia, and urolithiasis. We suggest appropriate management, including pain control, rehabilitation, surgery, and controlling other risk factors for UTI in older adults with OA to prevent subsequent UTI. Further studies, including recruiting data of daily activity and validation in other nations, are warranted.
