Abstract: A flower-like hematite microstructure has been successfully prepared by a facile hydrothermal synthesis method without using any organic solvents or templates. It is revealed that the flower-like hematite microstructure consists of well-crystallized nanorods with the average diameter of about 100±15 nm and average length of about 900±100 nm growing from the centers. A possible growth mechanism of the flower-like \( \alpha \)-Fe\(_2\)O\(_3\) microstructure is proposed and discussed. The photocatalytic properties of the synthesized flower-like hematite nanostructure are evaluated using the degradation of rhodamine B in aqueous solution.

Keywords: hematite; nanostructure; hydrothermal synthesis

1 Introduction

Due to their low cost and environmental friendliness, hematite or \( \alpha \)-Fe\(_2\)O\(_3\) has been the subject of intense research for several decades. Hematite nanostructures are extensively studied for solar water splitting [1,2], new lithium battery materials [3], water treatment [4], etc. Over the past few years, various hematite nanostructures, such as nanoparticles [5], nanowires [6] and nanotubes [7] have been prepared with a variety of methods. These methods demonstrate that morphological control of hematite can be achieved by using different solvents. However, these common organic-phase methods are hazardous because these precursors are toxic and difficult to handle under normal conditions. Moreover, these approaches are unsuitable in terms of scaling up for industrial production owing to the high cost and large volume of chemical wastes generated [8].

Three-dimensional (3D) hierarchical architectures which are constructed from one-dimensional and two-dimensional nanoscaled building blocks have aroused extensive attention owing to their enhanced physical/chemical properties and superior device performances [9]. Such hierarchical architectures combine the features of nanoscaled building units and can exhibit unique properties that are distinct from those of the low-dimensional structures. Therefore, researchers continue to seek straightforward and inexpensive chemical methods for controllable production of 3D hierarchical functional nanostructures. Thus, it remains a significant challenge to develop a simple, effective and template-free method to construct complex 3D hierarchical structures at relatively low temperatures.

Herein, novel 3D flower-like hematite microstructure was prepared via a simple hydrothermal method without using any templates at a relatively low temperature. The structure and morphology of the resulting hematite microstructures were characterized by X-ray diffraction (XRD), field emission scanning

electron microscopy (FESEM), transmission electron microscopy (TEM) and energy-dispersive X-ray spectroscopy (EDX). The photocatalytic properties of synthesized 3D flower-like hematite were investigated using the degradation of rhodamine B in aqueous solution. The present study reveals a fast and reliable approach for building hierarchically self-assembled hematite microstructures.

2 Experimental

Analytical grade FeCl₃ (97.0%) and NaNO₃ (99.0%) were purchased from Sigma-Aldrich Corporation and were used without further purification. In a typical synthesis method, FeCl₃ (0.015 mol) and NaNO₃ (0.1 mol) were dissolved in 40 mL of deionized (DI) water. Precipitates were prepared by heating the aqueous solution of corresponding metal salts in sealed glass bottle at 100°C for 2 h. The resulting colloidal solution was centrifuged at 5000 rpm for 10 min. The precipitates were washed 3 times with ethanol and DI water, dried and calcined in air at 700°C for 1 h.

The structure of the prepared powders was examined by XRD (Bruker D8 Discover) using Cu Kα radiation (λ = 0.15405 nm) at 2θ scan range of 20°–60°. The morphology of the particles was characterized by FESEM (Hitachi S-4700) and TEM (JEOL JEM-2100F). Elemental analysis was carried out using EDX (Horiba, 6853-H). The thermogravimetric (TG) analysis was performed with a Netzsch-STA-449C differential scanning calorimetry–thermogravimetric analyzer in air atmosphere from room temperature up to 700°C at elevating temperature rate of 10°C/min. The prepared hematite microstructure was further used as a photocatalyst for the rhodamine B (RB) aqueous solution degradation. In a typical process, 50 mg of the flower-like hematite sample was added to 100 mL of 1.0×10⁻⁵ M RB solution and then magnetically stirred in the dark for 30 min, which made the adsorption of RB on the flower-like sample reach equilibrium. The solution was then exposed to ultraviolet (UV) irradiation with a distance of 20 cm from a 250 W high-pressure Hg lamp at room temperature. Every 5 min, 5 mL of solution was withdrawn from the beaker and then centrifuged. The concentrations of RB in the supernatants were analyzed using a UV–Vis spectrophotometer (Evolution 220) at a wavelength of 553 nm. All measurements were performed at room temperature.

3 Results and discussion

The morphology and elemental analysis of the prepared flower-like hematite microstructure were examined by FESEM and EDX. As shown in Fig. 1, the sample is composed of uniform flower-like architectures with the diameter of 3–5 μm. The magnified image of individual flower-like architecture (inset of Fig. 1) reveals that each structure is composed of many aligned nanorods with the average diameter of about 100±10 nm and average length of about 900±100 nm growing from the center. EDX analysis of the structure reveals only the presence of Fe and O in the formed microstructure (Pt peaks appear due to platinum coating on the sample). This indicates that the material is clean, and no sodium, neither nitrate or chloride contamination, is detected which indicates a great improvement compared to solvothermal or template-based synthesis. It is also found that the reaction time and FeCl₃ concentration have no significant effects on the morphology of products (Fig. S1 in the Electronic Supplementary Material (ESM)). However, a minimum time of 2 h is needed to prepare the flower-like FeOOH microstructure. Thus, one can
synthesize the flower-like microstructure within a relatively short time frame. TG analysis (Fig. S2 in the ESM) shows that the total mass loss corresponding to the complete transformation of FeOOH into $\alpha$-Fe$_2$O$_3$ should be around ~20%, which is fully achieved at 700 °C. Further temperature rising probably leads to a strong agglomeration and is not investigated in the present study.

The microstructure of the as-prepared flower-like $\alpha$-Fe$_2$O$_3$ sample is further examined by TEM. Figure 2(a) displays the representative TEM image of the obtained $\alpha$-Fe$_2$O$_3$ flower-like pattern. TEM micrograph clearly indicates that the sample is built up with radially aligned nanorods, which is consistent with the observation from the FESEM image. The high resolution TEM image (inset of Fig. 2(a)) of the selected area marked with a white rectangle shows a crystalline character with a lattice spacing of 0.248 nm, which is close to the interplanar distance for the (110) plane of $\alpha$-Fe$_2$O$_3$. Figure 2(b) displays the typical XRD pattern of the flower-like $\alpha$-Fe$_2$O$_3$ sample, and all the peaks can be indexed to the rhombohedral phase of $\alpha$-Fe$_2$O$_3$ (JCPDS No. 33-0664). The narrow and sharp peaks suggest that the obtained $\alpha$-Fe$_2$O$_3$ is highly crystalline. The crystallite size of the $\alpha$-Fe$_2$O$_3$ sample evaluated by Scherrer’s equation for the strongest peak (104) is 27.3 nm, suggesting that nanorods are consisted of smaller crystallites. The possible growth mechanism of the flower-like $\alpha$-Fe$_2$O$_3$ is schematically shown in Fig. 3. It is well known that the kinetics of Fe$^{3+}$ hydrolysis in aqueous solutions and the morphologies and properties of solid hydrolytic products strongly depend on the nature of the anion involved. Therefore, the use of NaNO$_3$ is crucial in the experiment. At the first stage, iron(III)-oxyhydroxide particles are produced by forced hydrolysis of iron(III) chloride. With the heat-treatment proceeding, the particles become more spherical, since a spherical shape is optimal from an energetic point of view. As the heat-treated time prolongs, the crystals continue to grow by combining with the remaining primary particles, probably due to Ostwald ripening. Finally, nanorods form, grow and merge with each other, forming the flower-like structure.

The photocatalytic performance of the flower-like $\alpha$-Fe$_2$O$_3$ sample is investigated by monitoring the rhodamine B (RB) aqueous solution degradation under UV irradiation. For comparative purposes, the photodegradation efficiencies of RB mediated by commercially available hematite powders and without any photocatalyst under UV irradiation are also investigated. The changes in the concentration of RB with UV irradiation time are plotted and shown in Fig. 4. In the absence of any catalyst, the concentration of RB decreases gradually and about 63% of RB is degraded under UV irradiation within 60 min. The commercial hematite powders show very weak photocatalytic activity under UV irradiation (71% of
RB within 60 min. However, the concentration of RB decreases dramatically when 50 mg of the flower-like α-Fe$_2$O$_3$ sample is added and the total degradation of RB is completed within 35 min (Fig. S3 in the ESM). The superior photocatalytic activity of the flower-like α-Fe$_2$O$_3$ in comparison to the commercial hematite could be attributed to its high surface area. It is generally accepted that the catalytic process is mainly related to the adsorption and desorption of molecules on the surface of the catalyst. The high specific surface area of the catalyst could result in more unsaturated surface coordination sites exposed to the reactant molecules for catalytic reactions.

4 Conclusions

In summary, flower-like α-Fe$_2$O$_3$ microstructure has been successfully fabricated by simple hydrothermal method following by thermal calcination in air. FESEM and TEM characterizations confirm that the flower-like α-Fe$_2$O$_3$ microstructure is composed of self-assembled nanorods of about 100 nm in diameter. The prepared flower-like microstructure shows high photocatalytic activity for the degradation of RB under UV irradiation. This method may present a simple approach for the controlled synthesis of other 3D structures.
