CONNECTED TURÁN NUMBER OF TREES

YAIR CARO, BALÁZS PATKÓS, AND ZSOLT TUZA

Abstract. As a variant of the much studied Turán number, $\text{ex}(n, F)$, the largest number of edges that an $n$-vertex $F$-free graph may contain, we introduce the connected Turán number $\text{ex}_c(n, F)$, the largest number of edges that an $n$-vertex connected $F$-free graph may contain. We focus on the case where the forbidden graph is a tree. The celebrated conjecture of Erdős and Sós states that for any tree $T$, we have $\text{ex}(n, T) \leq (|T| - 2) \frac{n^2}{2}$. We address the problem how much smaller $\text{ex}_c(n, T)$ can be, what is the smallest possible ratio of $\text{ex}_c(n, T)$ and $(|T| - 2) \frac{n^2}{2}$ as $|T|$ grows. We also determine the exact value of $\text{ex}_c(n, T)$ for small trees, in particular for all trees with at most six vertices. We introduce general constructions of connected $T$-free graphs based on graph parameters as longest path, matching number, branching number, etc.

1. Introduction

One of the most studied problems in extremal graph theory is to determine the Turán number $\text{ex}(n, F)$, the largest number of edges that an $n$-vertex graph can have without containing a subgraph isomorphic to $F$. In this paper, we study a variant of this parameter: the connected Turán number $\text{ex}_c(n, F)$ is the largest number of edges that a connected $n$-vertex graph can have without containing $F$ as a subgraph. Observe that if $F$ is 2-edge-connected, then any maximal $F$-free graph $G$ is connected, as if $G$ had at least two components, then adding an edge between them would not create any copy of $F$. Also, if the chromatic number of $F$ is at least 3, then by the famous theorem by Erdős, Stone, and Simonovits [5, 6], we know that $\text{ex}(n, F)$ is attained asymptotically (and for some graphs precisely) at the Turán graph that is connected. These two observations imply the following proposition.

Proposition 1.1.

1. If all components of $F$ are 2-edge-connected, then $\text{ex}(n, F) = \text{ex}_c(n, F)$.
2. If $\chi(F) \geq 3$, then $\text{ex}_c(n, F) = (1 + o(1)) \text{ex}(n, F)$.

The asymptotics of $\text{ex}(n, F)$ is unknown for most bipartite $F$ (for a general overview of the so-called degenerate Turán problems, see the survey by Füredi and Simonovits [7]). And we do not know the relationship of $\text{ex}(n, F)$ and $\text{ex}_c(n, F)$ for most bipartite $F$ that are not 2-edge-connected. There is a relatively large literature on the Turán number of forests (see e.g. [3, 10, 11, 13, 14]), and in many cases the extremal graphs turned out to be connected, so for those forests $F$, we have $\text{ex}(n, F) = \text{ex}_c(n, F)$. A wide and important class of connected non-2-edge-connected graphs is the set of trees. A famous conjecture of Erdős and Sós (that

Tuza’s research is partially supported by NKFIH grant SNN 129364.
appeared in print first in [4]) states that any $n$-vertex graph with more than $\frac{(k-2)n}{2}$ edges contains any tree $T$ on $k$ vertices. A proof was announced in the early 1990’s by Ajtai, Komlós, Simonovits, and Szemerédi, but only arguments of special cases have appeared. A recent survey of these and other degree conditions that imply embeddings of trees is [12]. The universal construction that shows the tightness of the Erdős–Sós conjecture is the union of vertex-disjoint cliques of size $k - 1$. This is not a connected graph and we are only aware of one result concerning $\text{ex}_c(n, T)$ (but there exist results on Turán problems in connected host graphs, see e.g. [2]). We denote by $P_k$ the path on $k$ vertices. The value of $\text{ex}_c(n, P_k)$ was determined by Kopylov, and independently by Balister, Győri, Lehel, and Schelp with the latter group also showing the uniqueness of extremal constructions.

**Theorem 1.2** (Kopylov [9], Balister, Győri, Lehel, Schelp [11]). If $G$ is an $n$-vertex connected graph that does not contain any paths on $k + 1$ vertices, then

$$e(G) \leq \max\left\{\left(\frac{k - 1}{2}\right) + n - k + 1, \left(\frac{k + 1}{2}\right) + \left(\frac{k - 1}{2}\right) \left(n - \left\lceil\frac{k + 1}{2}\right\rceil\right)\right\}$$

holds.

We shall now present the various results obtained concerning $\text{ex}_c(n, T)$. Lower bound constructions are given in Section 2 and exact determination of $\text{ex}_c(n, T)$ including all trees up to 6 vertices is included in Section 3.

Our first result gathers several constructions, all based on some graph parameters, that provide lower bounds on $\text{ex}_c(n, T)$. For those parameters we use the following notation.

**Definition 1.3.**

- $\ell(G)$ denotes the number of vertices in a longest path in $G$.
- $p(G)$ denotes the maximum number of vertices in a path $P$ of $G$ such that for all $x \in V(P)$ we have $d_G(x) \leq 2$.
- $\Delta(G)$ and $\delta(G)$ denote the maximum and the minimum degree in $G$.
- $\nu(G)$ denotes the number of edges in a largest matching of $G$.
- $\delta_2(T)$ denotes the smallest degree in $T$ that is larger than 1.
- For a vertex $v \in V(T)$ let $m_T(v)$ be the size of largest component of $T - v$ and let $m(T) = \min\{m_T(v) : v \in V(T)\}$.
- For a vertex $v \in V(T)$ let $m_{T,2}(v)$ be the sum of the sizes of two largest components of $T - v$ and let $m_{2}(T) = \min\{m_{T,2}(v) : v \in V(T)\}$.
- For an edge $e = xy \in E(G)$ we write $w(e) = \min\{d_G(x), d_G(y)\}$ and define $w(G) = \max\{w(e) : e \in E(G)\}$.

**Proposition 1.4.** Suppose $T$ is a tree on $k \geq 4$ vertices.

1. $\text{ex}_c(n, T) \geq \left(\frac{\ell(T)}{2}\right) + \left\lceil\frac{\ell(T)-2}{2}\right\rceil \left(n - \frac{\ell(T)}{2}\right)$.
2. $\text{ex}_c(n, T) \geq \left(\frac{k-2p(T)-3}{2}\right) + p(T) + 2\left\lceil\frac{n}{k-\rho(T)}\right\rceil$. Furthermore, if $T$ contains at least two vertices of degree at least three, then $\text{ex}_c(n, T) \geq \frac{(k-\rho(T)-1)+p(T)+2}{k}n - O(k)$. 
(3) \( \text{ex}_c(n, T) \geq \left\lfloor \frac{n(\Delta(T) - 1)}{2} \right\rfloor. \)
(4) \( \text{ex}_c(n, T) \geq (\nu(T) - 1)(n - \nu(T) + 1) + \binom{\nu(T)}{2}. \)
(5) If \( T \) is not a star and \( \delta_2(T) > 2 \), then \( \text{ex}_c(n, T) \geq \left\lfloor \frac{n-1}{k-1} \right\rfloor \left( \binom{k-2}{2} + \delta_2(T) - 1 \right). \)
(6) If the bipartition of \( T \) consists of classes of sizes \( a \) and \( b \) with \( a \leq b \), then \( \text{ex}_c(n, T) \geq (a - 1)(n - a + 1). \)
(7) If \( T \) is not a path, then \( \text{ex}_c(n, T) \geq n - 1 + \left\lfloor \frac{n-1}{m(T)-1} \right\rfloor \left( m(T) - 1 \right) \).
(8) \( \text{ex}_c(n, T) \geq \left\lfloor \frac{n}{k-m(T)} \right\rfloor \left( 1 + \binom{k-m(T)}{2} \right). \)
(9) \( \text{ex}_c(n, T) \geq (w(T) - 1)(n - w(T) + 1). \)

According to the Erdős–Sós conjecture, \( \text{ex}(n, T) = \frac{k-2}{2} n + O_k(1) \). We would like to know how much smaller \( \text{ex}_c(n, T) \) can be than \( \text{ex}(n, T) \). For any tree \( T \) we introduce

\[ \gamma_T := \limsup_n \frac{2}{|T| - 2} \frac{\text{ex}_c(n, T)}{n} \]

where \( |T| \) denotes the number of vertices in \( T \). It is well-known that any graph with average degree at least \( 2d \) contains a subgraph with minimum degree at least \( d \). Also, any tree on \( k \) vertices can be embedded to any graph with minimum degree at least \( k \). This shows that \( \gamma_T \leq 2 \) for any tree \( T \) on \( k \) vertices. The Erdős–Sós conjecture would imply \( \gamma_T \leq 1 \).

Let \( T_k \) denote the set of trees on at least \( k \) vertices. We write \( \gamma_k := \inf\{ \gamma_T : T \in T_k \} \) and \( \gamma := \lim_{k \to \infty} \gamma_k \) (the limit exists as \( \gamma_k \) is monotone increasing).

**Theorem 1.5.** The following upper and lower bounds hold: \( \frac{1}{3} \leq \gamma \leq \frac{2}{3} \).

Finally, we determine \( \text{ex}_c(n, T) \) for all trees on \( k \) vertices with \( 4 \leq k \leq 6 \) (note that there do not exist \( P_3 \)-free connected graphs), and some trees on 7 vertices. We need some notation first.

\( D_{a,b} \) denotes the *double star* on \( a + b + 2 \) vertices such that the two non-leaf vertices have degree \( a + 1 \) and \( b + 1 \). The *star with \( k \) leaves* is denoted by \( S_k \). \( S_{a_1,a_2,...,a_j} \) with \( j \geq 3 \) denotes the *spider* obtained from \( j \) paths with \( a_1, a_2, \ldots, a_j \) edges by identifying one endpoint of all paths. So \( S_{a_1,a_2,...,a_j} \) has \( 1 + \sum_{i=1}^{j} a_i \) vertices and maximum degree \( j \). The only vertex of degree at least 3 is the center of the spider, the maximal paths starting at the center are the *legs* of the spider. \( M_{n} \) denotes the matching on \( n \) vertices (so if \( n \) is odd, then an isolated vertex and \( \left\lfloor \frac{n}{2} \right\rfloor \) isolated edges).

For graphs \( H \) and \( G \), their join is denoted by \( H + G \), their disjoint union is denoted by \( H \cup G \). For a graph \( H \) and a positive integer \( k \), \( kH \) denotes the pairwise vertex-disjoint union of \( k \) copies of \( H \).

The values of \( \text{ex}_c(n, P_{k+1}) \) were determined by Theorem 1.2 and for \( k \geq 3 \), the statement \( \text{ex}_c(n, S_k) = \left\lfloor \frac{n(k-1)}{2} \right\rfloor \) follows from Proposition 1.4 (3) and that the degree-sum of an \( S_k \)-free graph is at most \( n(k-1) \). So in the next theorem, we only list those trees that are neither paths nor stars. In particular, all trees have 5 or 6 vertices.
Theorem 1.6. For non-star, non-path trees with 5 or 6 vertices, the following exact results are valid.

(1) For any $T = S_{2,1,...,1}$ we have $\text{ex}_c(n, T) = \left\lfloor \frac{n(n(T) - 1)}{2} \right\rfloor$ if $n \geq |T|$. In particular, $\text{ex}_c(n, S_{2,1,1}) = n$ if $n \geq 5$ and $\text{ex}_c(n, S_{2,1,1,1}) = \left\lfloor \frac{3n}{2} \right\rfloor$ if $n \geq 6$.

(2) We have $\text{ex}_c(n, D_{2,2}) = 2n - 4$ if $n \geq 6$.

(3) We have $\text{ex}_c(n, S_{3,1,1}) = \left\lfloor \frac{3(n-1)}{2} \right\rfloor$ if $n \geq 7$ and $\text{ex}(6, S_{3,1,1}) = 9$.

(4) We have $\text{ex}_c(n, S_{2,2,1}) = 2n - 3$ if $n \geq 6$.

| Number of vertices | Tree | $\text{ex}_c(n, T)$ | Construction |
|--------------------|------|---------------------|--------------|

| $SD_{2,2}$ | $\frac{6n}{5} - O(1)$ | Prop. [1,6] (2) |

Table 2. Exact values and lower bounds on $\text{ex}_c(n, T)$ for trees with 7 vertices

Let $D_{2,2}^*$ be the tree obtained from $D_{2,2}$ by attaching a leaf to one leaf of $D_{2,2}$.

Theorem 1.7. We have $\text{ex}_c(D_{2,2}^*) = 2n - 3$ for all $n \geq 7$, and $\text{ex}_c(D_{2,2}^*) = \left(\begin{array}{c} n \\ 2 \end{array}\right)$ for $1 \leq n \leq 6$.

Theorem 1.8. We have $\text{ex}_c(S_{2,2,2}) = 2n - 2$ for all $n \geq 7$, and $\text{ex}_c(S_{2,2,2}) = \left(\begin{array}{c} n \\ 2 \end{array}\right)$ for $1 \leq n \leq 6$.

Theorem 1.9. We have $\text{ex}_c(S_{3,2,1}) = 2n - 3$ for all $n \geq 7$, and $\text{ex}_c(S_{3,2,1}) = \left(\begin{array}{c} n \\ 2 \end{array}\right)$ for $1 \leq n \leq 6$. 
Theorem 1.10. For any $T = S_{3,1,\ldots,1}$ with $\Delta(T) \geq 4$, we have $\text{ex}_c(n, T) = \left\lfloor \frac{(\Delta(T)-1)n}{2} \right\rfloor$ if $n$ is large enough.

For a better overview, we include tables with previous results, our results and open cases for trees up to 7 vertices. $SD_{2,2}$ denotes the tree on 7 vertices obtained from the double star $D_{2,2}$ by subdividing the edge connecting its two centers.

2. Constructions

Proof of Proposition 1.4. For all lower bounds we need constructions.

To see (1), we use the construction of Kopylov and Balister, Gy˝ori, Lehel, and Schelp: let $G_{n,k,s}$ be the graph defined by partitioning $V = X \cup Y \cup Z$ with $|X| = k - 2s$, $|Y| = s$, and $|Z| = n - k + s$ such that $G[X \cup Y]$ is a clique and the set of all other edges of $G_{n,k,s}$ is $\{(yz) : y \in Y, z \in Z\}$. If $k > 2s$, then $G_{n,k,s}$ is $P_{k+1}$-free. Plugging $k = \ell(T)$ and $s = \left\lfloor \frac{4\ell(T) - 1}{2} \right\rfloor$ proves the claim.

For the general lower bound of (2), we construct a graph $G(V, E)$ as follows: let $s := \left\lfloor \frac{n}{k-p(T) - 1} \right\rfloor$ and let $V$ be partitioned into $K_1 \cup P_1 \cup K_2 \cup P_2 \cup \cdots \cup K_s \cup P_s$ with $|K_i| = k - 2p(T) - 3$ for all $1 \leq i \leq s$, $|P_i| = p(T) + 1$ for all $1 \leq i < s$, $G[K_i]$ is a clique for all $i$. Every clique $K_i$ contains a special vertex $x_i$, and $G[\{x_i, x_{i+1}\} \cup P_i]$ is a path with end vertices $x_i$ and $x_{i+1}$ (with $x_{s+1} = x_1$). Then $G$ cannot contain $T$, as a partial copy of $T$ could contain the vertices of a $K_i$ and then at most $p(T)$ vertices from both of $P_i-1$ and $P_i$, so at least one vertex of $T$ cannot be embedded.

To see the furthermore part of (2), we have the following construction $G$: we partition the vertex set of $G$ into $\{v\} \cup \bigcup_{i=1}^s (C_i \cup P_i)$, where $s = \left\lfloor \frac{n}{k-p(T)} \right\rfloor$ with $|C_i| = k - p(T) - 1$, $|P_i| = p(T) + 1$ for all $1 \leq i < s$, and $|P_i| \leq p(T) + 1$ and if $|C_i| > 0$, then $|P_i| = p(T) + 1$. The edges of $G$ are defined such that $G[\{v\} \cup \bigcup_{i=1}^s P_i]$ is a spider with center $v$ and legs $P_i$, $G[C_i]$ is a clique and exactly one vertex of $C_i$ is connected to the leaf of the leg in $P_i$. The number of edges adjacent to $C_i \cup P_i$ is $\left(\frac{k-p(T)-1}{2}\right) + p(T) + 2$, therefore $e(G)$ is as claimed. Finally, to see that $G$ is $T$-free, observe that as $T$ contains at least two vertices of degree at least 3, if $G$ contained a copy of $T$, then this copy should contain a vertex $u$ from one of the $C_i$s. Also, such a copy cannot contain all vertices of $P_i$ as $p(T) < |P_i|$. Therefore, the vertices of the copy of $T$ should be contained in $|C_i| + |P_i| - 1 < k$ vertices - a contradiction.

To see (3), it is known that there exist connected $k$-regular graphs on $n$ vertices if $nk$ is even and there exist connected $n$-vertex graphs with all but one vertex having degree $k$ and the remaining vertex degree $k - 1$ if $nk$ is odd. A connected $(\Delta(T) - 1)$-regular or nearly $(\Delta(T) - 1)$-regular graph clearly does not contain $T$.

The lower bound of (4) is shown by $K_{\nu(T)-1} + E_{n-\nu(T)+1}$ that has matching number $\nu(T) - 1$ and therefore cannot contain $T$.

The lower bound of (5) is shown by the following construction of a connected $n$-vertex $T$-free graph $G$: we partition the vertex set of $G$ into $\{v\} \cup \bigcup_{i=1}^s (A_i \cup \{x_i\})$ and $|A_i| = k - 2$ for all $i = 1, 2, \ldots, \left\lfloor \frac{n}{k-2} \right\rfloor$. The edges of $G$ are defined as follows: $G[A_i]$ is a clique, $v$ is adjacent to all $x_i$, and $x_i$ is adjacent to $\delta_2(T) - 2$ vertices of $A_i$, so $d_G(x_i) = \delta_2(T) - 1$. We claim that...
$G$ is $T$-free. Indeed, as $G - v$ has components of size at most $k - 1$, a copy of $T$ must contain $v$. As $T$ is not a star, at least one of $v$’s neighbors is not a leaf and so its degree should be at least $\delta_2(T)$. But all $v$’s neighbors are $x_i$ vertices that have degree $\delta_2(T) - 1$ in $G$.

The construction yielding the lower bound of (6) is $K_{a-1,n-a+1}$ as it does not contain bipartite graphs with both parts having at least $a$ vertices.

The construction yielding the lower bound of (7) is $G = K_1 + (rK_{m(T)-1} \cup K_s)$, where $r = \lfloor \frac{n}{m(T)} \rfloor$ and $s \geq 0$. Indeed, if $G$ contained a copy of $T$, then this copy should contain the vertex $v$ of $K_1$ as otherwise $T$ would be contained in $m(T) - 1$ vertices. But then we cannot embed the largest branch pending on $v$ as it has size at least $m(T)$.

To obtain the construction yielding the lower bound of (8), we partition the vertex set to $A_1, A_2, \ldots, A_s, A_{s+1}$ with $s = \lfloor \frac{n}{k-m_2(T)} \rfloor$ and $|A_i| = k - m_2(T)$ for all $i = 1, 2, \ldots, s$. As $T$ is not a path, we have $k - m_2(T) \geq 2$, so in each $A_i$ we can pick two distinct vertices $x_i, y_i$, maybe with the exception of $A_{s+1}$. Then we define $G$ as a “cycle of cliques”, so $G[A_i]$ is a clique for all $i$, and $x_iy_{i+1}$ is an edge (formally there should be three cases depending whether $A_{s+1}$ has size 0, 1, or at least 2). To see that $G$ is $T$-free, consider the vertex $v$ with $m_2(T) = m_{T,2}(v)$, i.e. the largest two components $C_1, C_2$ in $T - v$ have a total size of $m_2(T)$. Suppose $G$ contains a copy of $T$ and the vertex playing the role of $v$ belongs to $A_i$. Then, as there are only two edges leaving $A_i$, $T$ apart from two components of $T - v$ must be embedded into $A_i$. Moreover, since the two edges leave from distinct vertices, at least one vertex of the two exceptional components must also be embedded to $A_i$. So $A_i$ should contain at least $k - m_2(T) + 1$ vertices — a contradiction. (If $i = s + 1$ and $x_i = y_i$, then we have the same contradiction, as then $A_{s+1}$ should contain at least $k - m_2(T)$ vertices, but $A_{s+1}$ is strictly smaller than that.)

The construction yielding the lower bound of (9) is $K_{w(T)-1,n-w(T)+1}$ as all its edges have weight $w(T) - 1$ and thus $K_{w(T)-1,n-w(T)+1}$ cannot contain $T$. □

3. Proofs

We start by proving Theorem 1.3. It will be a consequence of the following two results.

**Theorem 3.1.** For any tree $T$ on $k$ vertices, we have $\text{ex}_c(n, T) \geq \lceil \frac{k}{6} \rceil n$ if $n$ is large enough.

**Proof.** **Case I:** $m(T) > \lceil k/3 \rceil$.

Then by Proposition 1.3 (7) we have

$$\text{ex}_c(n, T) \geq n - 1 + \left\lfloor \frac{n - 1}{m(T) - 1} \right\rfloor \left( m(T) - 1 \right) \geq (n - 1) \left( 1 + \frac{\lceil k/3 \rceil - 1}{2} \right) \geq n \left\lfloor \frac{k}{6} \right\rfloor,$$

if $n$ is large enough.

**Case II:** $m(T) \leq \lceil k/3 \rceil$.

Let $v$ be a vertex such that $T - v$ contains only components of size at most $\lceil k/3 \rceil$ for some vertex $v$. Let $n = s\lceil k/3 \rceil + r$ with $r < \lceil k/3 \rceil$. Consider the graph $G$ on vertex set $A_1 \cup A_2 \cup \cdots \cup A_{s+1}$ with $|A_i| = \lceil k/3 \rceil$ for all $1 \leq i \leq s$ and $|A_{s+1}| = r$ such that $G[A_i]$ is a
Theorem 3.2.

A of the vertices of $T_{k}$.

Theorem 3.2 (2) with taking $a$.

Let $x$.

$x$ of $T$.

The constructions giving the lower bounds are connected (nearly) regular graphs of degree $\Delta(T)$.

We obtained that $\Delta(G)$.

Assume first that there exists a vertex $x$.

Proof. The lower bound of $\lfloor \frac{(k-a)n}{2} \rfloor$ follows from Proposition 1.3 (3), while, as $\ell(B(k,a)) = a + 1$, Proposition 1.2 (1) yields the lower bound $\lfloor \frac{a-1}{2} \rfloor$.

To see the upper bound of (2), let $G(V,E)$ be an $n$-vertex $B(k,a)$-free graph with $a \leq k/3$. Assume first that there exists a vertex $x$ with $d_G(x) \geq k - 1$. We claim that $G[V \setminus \{x\}]$ does not contain a path on $2a - 3$ vertices. Indeed, suppose to the contrary that $y_1, y_2, \ldots, y_{2a-3}$ is a path in $G[V \setminus \{x\}]$. Then as $G$ is connected, there exists a path $P$ from $x$ to some $y_j$ that does not contain any other $y_i$. Then either $x, P, y_j, y_{j+1}, \ldots, y_{2a-3}$ contains at least $a$ vertices. So $x$ and the first $a - 1$ of them together with the other neighbors of $x$ form a copy of $B(k,a)$ — a contradiction. Theorem 1.2 implies that if $n$ is large enough, then $e(G) \leq n - 1 + [\frac{2a-1}{2}]n \leq an \leq \lfloor \frac{k-2}{2} \rfloor n$. This finishes the proof in this case.

Assume finally that $\Delta(G) \leq k - 2$. Then if $n$ is large enough, every vertex $x$ of $G$ is the endpoint of a path on $a \cdot k$ vertices, since $G$ is connected and have maximum degree at most $k - 2$. Suppose towards a contradiction that $G$ contains a vertex $x$ with $d_G(x) = d \geq k - a + 1$. Let $z_1, z_2, \ldots, z_d$ be the neighbors of $x$ and let $x, y_2, y_3, \ldots, y_{a-1}$ be a path $P$. Then $y_2$ is one of the $z_j$’s, and as $d \leq k - 2$, there must exist $z_j$ such that $z_j \in P$, say $z_j = y_i$ and either $y_{i-1}, y_{i-2}, \ldots, y_{i-a+2}$ or $y_{i+1}, y_{i+2}, \ldots, y_{i+a-2}$ are not neighbors of $x$. Then $x$, these $y_i$s and the neighbors of $x$ form a $B(k,a)$.

We obtained that $\Delta(G) \leq k - a$ must hold, which implies $e(G) \leq \lfloor \frac{(k-a)n}{2} \rfloor$ as claimed.

Proof of Theorem 1.5. The lower bound follows from Theorem 3.1 the upper bound from Theorem 3.2 (2) with taking $a = \lfloor k/3 \rfloor$.

We continue by proving Theorem 1.6. We restate and prove its parts separately.

Theorem 3.3. For $T = S_{2,1,\ldots,1}$, we have $\text{ex}_c(n, T) = \lfloor \frac{n(\Delta(T)-1)}{2} \rfloor$.

Proof. The constructions giving the lower bounds are connected (nearly) regular graphs of degree $\Delta(T) - 1$.

If $T = S_{2,1,\ldots,1}$, then the upper bound proof is a special case of Theorem 3.2 but for completeness, we give a simpler proof of this case. If $G$ is a connected, $n$-vertex, $T$-free graph
and for some $x$ we have $d_G(x) \geq \Delta(T)$, then $G$ is the star. Indeed, the neighbors of $x$ can be adjacent only to other neighbors of $x$, otherwise $T$ would be a subset of $G$. So by connectivity $N_G[x] = V(G)$. But then if there is at least one edge between two neighbors of $x$, then, as $|V(G)| \geq |V(T)|$, again $T$ would be a subgraph of $G$. The star has fewer edges than the claimed maximum, so to have $\text{ex}_e(n, T)$ edges, $G$ must be (nearly) $(\Delta(T) - 1)$-regular.  

**Theorem 3.4.** We have $\text{ex}_e(n, D_{2,2}) = 2n - 4$ for any $n \geq 6$.

*Proof.* To see the lower bound, observe that $K_{2,n-2}$ is $D_{2,2}$-free as $w(K_{2,n-2}) = 2$, while $w(D_{2,2}) = 3$.

To see the upper bound, observe first that all connected graphs with 6 vertices and at least 9 edges contain a copy of $D_{2,2}$ as can be checked in the table of graphs of [8] on pages 222–224.

Suppose there exists a minimum counterexample: a connected graph $G$ on $n \geq 7$ vertices and $e(G) \geq 2n - 3$ edges with no copy of $D_{2,2}$. We consider several cases.

**Case I:** $\delta(G) \leq 2$ and there is a vertex $v$ of degree at most 2 which is not a cut-point.

Delete a vertex $v$ of degree 1 or 2 to obtain a connected $H = G \setminus v$ with $|H| \geq 6$. By minimality $e(H) \leq 2(n - 1) - 4$ and $2n - 3 \leq e(G) \leq e(H) + 2 \leq 2(n - 1) - 4 + 2 = 2n - 4$, a contradiction.

**Case II:** $\delta(G) = 2$ and every vertex of degree 2 is a cut-point.

Consider $v$ of degree 2 such that in $H = G - v$ out of the two components $A$ and $B$, $|A|$ is as small as possible. Let $w$ be the vertex in $A$ adjacent to $v$ and let $z$ be the vertex in $B$ adjacent to $v$.

If $|A| \geq 6$ then by minimality of $G$, $2n - 3 \leq e(G) \leq 2|A| - 4 + 2|B| - 4 + 2 = 2(|A| + |B| + 1) - 8 = 2n - 8$, a contradiction. Otherwise $3 \leq |A| \leq 5$ as $|A| \leq 2$ would imply $\delta(G) = 1$ and we were in Case I. Also, $|A| \geq 4$ as $|A| = 3$ would imply that $A$ must contain a vertex of degree 2 which is not a cut-point and we were in Case I again.

Suppose $|A| = 5$. If $d_G(w) = 2$ then $|A|$ is not minimum, so in the induced subgraph on $A$ all vertices have degree at least 2 and $d_G(w) \geq 3$. But then the induced graph on $A$ either contains a vertex of degree 2 which is not a cut-point and we are in Case I or all degrees in $G[A \cup \{v\}]$ (except for $v$) are at least 3. Then one can find a copy of $D_{2,2}$ with $w$ being one of the centers and $v$ being a leaf pending from $w$. Indeed, by the degree condition, $G[A \setminus \{w\}]$ contains a $C_4$, so if $N(w)$ contains two non-neighbor vertices $x, y$ of this $C_4$, then $x$ can be the other center of the copy of $D_{2,2}$ and $y$ the other leaf pending from $w$. Otherwise $w$ has exactly two neighbors in $A$, and then by the degree condition $G[A \setminus \{w\}]$ is $K_4$ and it is trivial to embed $D_{2,2}$.

Finally suppose $|A| = 4$. As $|B| \geq |A| = 4$, it follows that $B^* = B \cup \{v, w\}$ has at least 6 vertices and $|B^*| = n - 3$, and hence by minimality of $G$, $e(B^*)$ contains at most $2(n - 3) - 4$ edges and together with at most 6 edges in $A$ gives $e(G) \leq 2n - 10 + 6 = 2n - 4$ — a contradiction.

**Case III:** $\delta(G) \geq 3$.  

If all vertices are of degree 3, we have $3n/2$ edges, which is at most $2n-4$ for $n \geq 8$. For $n = 7$ this is impossible by parity, hence $\delta(G) \geq 3$ and $\Delta(G) \geq 4$. Consider an edge $e = xy$ with $d_G(y) = \Delta(G) \geq 4$ and $d_G(x) \geq 3$.

If $d_G(y) \geq 5$, then for $u, u' \in N(x)$ we have $|N(y) \setminus \{x, u, u'\}| \geq 2$, so $x$ and $y$ are centers of a copy of $D_{2,2}$. If $d_G(y) = 4$ and $d_G(x) = 4$ then either $x$ and $y$ have distinct neighbors $s$ not in $N[y]$ and $t$ not in $N[x]$ and we find a copy of $D_{2,2}$ with centers $x, y$, or $x$ and $y$ are twins having the same neighbors $a, b, c$ excluding themselves. But as $|G| \geq 7$, at least one vertex, say $a$, has a neighbor $d$ not adjacent to the other 4 vertices and then $a$ and $x$ can be centers of $D_{2,2}$ with $y$ and $d$ pending from $a$.

So we can assume that all vertices have degree 3 or 4 and vertices of degree 4 form an independent set $Q$. Let $P = V \setminus Q$, and consider the bipartite $G[P, Q]$ where $p + q = n$, $|P| = p$ and $|Q| = q$. Clearly, $4q = e(P, Q) \leq 3p$. Hence $3n = 3q + 3p \geq 7q$ and $q \leq 3n/7, p \geq 4n/7$. But then

$$e(G) = \frac{4q + 3p}{2} \leq \frac{12n/7 + 12n/7}{2} = \frac{12n}{7} < 2n - 3$$

for $n \geq 11$. So we are left with $n = 7, 8, 9, 10$.

For $n = 7$: $q \leq 3n/7 = 3$ and $q$ must be an integer. If $q = 3$, then $G = K_{4,3}$ containing $D_{2,2}$. The case $q = 2$ is impossible as the degree sum would be odd (by the number $p$ of odd-degree vertices). Hence $q = 1$ and $p = 6$. Consider a vertex $v$ of degree 4 and its neighbors $a, b, c, d$ all of degree 3. If $a$ is adjacent to a vertex outside $\{v, b, c, d\}$, then there is $D_{2,2}$. But as this holds for all of $a, b, c, d$ it means $A = \{v, a, b, c, d\}$ has no neighbor in $V \setminus A$ and $G$ is not connected.

For $n = 8$, we still have $q \leq \lfloor \frac{3n}{7} \rfloor = 3$ and $p \geq 5$. But $p = 5, 7$ are impossible, again due to parity, hence $q = 2$ and $p = 6$. Let $Q = \{a, b\}$ be the set of vertices of degree 4, and let $P = V \setminus Q$. If some vertex $x$ in $P$ is adjacent to both $a$ and $b$, then consider the only neighbor $z$ of $x$ in $P$. Here $a$ is adjacent to $x$ and three more vertices in $P$, so at least two vertices except $x$ and $z$ are neighbors of $a$ and $x$ can use $z$ and $b$ to obtain a copy of $D_{2,2}$ with centers $x$ and $a$. Hence every vertex in $P$ is adjacent to at most one vertex in $Q$, yielding $|P| \geq e(P, Q) = 2|Q| — a$ contradiction.

For $n = 9$, we have $q \leq \lfloor \frac{3n}{7} \rfloor = 3$. The case $q = 2$ is impossible by parity and $q = 1, p = 8$ implies $e(G) = (4 + 24)/2 = 14 = 2n - 4$ as stated by the theorem. So only $q = 3, p = 6$ is to be checked. Let $Q = \{a, b, c\}$ be the set of vertices of degree 4, and let $P = V \setminus Q$. If some vertex $v$ in $P$ has at least two neighbors in $Q$, say $a, b$, then we have a copy of $D_{2,2}$ with centers $v$ and $a$, as all the four neighbors of $a$ are in $P$ and at most two of them belong to $N[v]$. So every vertex in $P$ can have at most one neighbor in $Q$ and as in the previous case we have $|P| \geq e(P, Q) = 4|Q| — a$ contradiction.

For $n = 10$, $q \leq \lfloor \frac{3n}{7} \rfloor = 4$, and so parity of the degree sum implies $q = 4$ or $q = 2$. If $q = 2$ then $e(G) = (8 + 24)/2 = 16 = 2n - 4$ as stated in the theorem, so only $q = 4, p = 6$ remains to be checked.
Let $Q = \{a, b, c, d\}$ be the set of vertices of degree 4, and let $P = V \setminus Q$. If some vertex $v$ in $P$ has all its neighbors in $Q$, say $a, b, c$, then we obtain a copy of $D_{2,2}$ with centers $v$ and $a$. Otherwise, we have $4|Q| = e(P, Q) \leq 2|P|$, a contradiction. \hfill \Box

**Theorem 3.5.** $\text{ex}_c(n, S_{3,1,1}) = \left\lceil \frac{3(n-1)}{2} \right\rceil$ if $n \geq 7$ and $\text{ex}(6, S_{3,1,1}) = 9$.

*Proof.* The lower bounds are shown by $K_1 + M_{n-1}$ for $n \geq 7$ and by $K_{3,3}$ for $n = 6$. The former is $S_{3,1,1}$-free as shown in Proposition 4.7 with $m(S_{3,1,1}) = 3$. The graph $K_{3,3}$ is $S_{3,1,1}$-free as the bipartition of $S_{3,1,1}$ has a part of size 4.

To obtain the upper bound, we consider an $S_{3,1,1}$-free connected graph $G$. The general idea is to choose a longest cycle $C = v_1v_2, \ldots, v_k$ in $G$, and argue depending on its length $k$.

If $k = n$, then $C$ is a Hamiltonian cycle. It cannot have short chords; e.g. if $v_2v_4$ is an edge, then $S_{3,1,1}$ can have center $v_2$ and legs $v_2v_1, v_2v_3, v_2v_4v_5v_6$. Moreover if $n > 6$, then longer chords cannot occur either. Indeed, if $v_2v_j$ with $j = 5, \ldots, n-2$ is an edge, then $v_2$ with $v_j$ and its two successors can form the leg of length 3. Likewise for $j = 6, \ldots, n-1$ such a leg can be formed using the two predecessors of $v_j$, still keeping the legs $v_2v_1$ and $v_2v_3$. This excludes all chords if $n > 6$, hence $|E(G)| = n$. If $n = 6$, then antipodal vertices can be adjacent without creating any copy of $S_{3,1,1}$, but no other chords may occur. In this way we obtain the extremal graph $K_{3,3}$.

Assume next that $4 < k < n$. We show that this is impossible whenever $n \geq 6$. Since $G$ is connected, there is a vertex $x$ not in $C$ but having at least one neighbor in $C$. If e.g. $xv_2$ is an edge, we find $S_{3,1,1}$ with center $v_2$ and legs $xv_2, v_2v_1, v_2v_3v_4v_5$.

Assume now $k = 4$, $C = v_1v_2v_3v_4$, $n \geq 6$. If $P$ is any path with one end in $C$ and all its other vertices in $V(G) \setminus V(C)$, then $P$ can have no more than two edges, otherwise $S_{3,1,1}$ would be found, with the long leg in $P$ and the two short legs in $C$. We are going to prove that if $P$ is shorter than 3, the number of edges in $G$ is smaller than what is given in the theorem.

If $P$ has length 2, let $xyv_1$ be a path attached to $C$. Then the edges $xv_2, xv_3, xv_4, yv_2, yv_4$ cannot be present because $C$ is a longest cycle. Also the edges $v_1v_3$ and $v_2v_4$ are excluded because $G$ is $S_{3,1,1}$-free. This implies $|E(G)| \leq 8$ if $n = 6$. If $n > 6$, there should be a further vertex $z$ adjacent to $C \cup P$, but any edge from $z$ to $C \cup P$ would create an $S_{3,1,1}$. (For $zx$ the center is $v_1$, and for any other edge the center is the neighbor of $z$.) Hence $n > 6$ is impossible in this case.

Suppose that $P = yv_1$ is a single edge not extendable to a longer path outside $C$. Then a sixth vertex $x$ can only be adjacent to $v_2$ or $v_4$ (or both), otherwise an $S_{3,1,1}$ would occur. And also here, it is not possible to extend this graph to a connected graph of order 7 without creating an $S_{3,1,1}$ subgraph. Hence $n = 6$. Moreover, the diagonals of $C$ must be missing; e.g. the edges $xv_2$ and $v_2v_4$ would yield $S_{3,1,1}$ with center $v_2$ and legs $xv_2, v_2v_3, v_2v_4v_1y$. Thus the number of edges is only 4 plus the degree sum of $x$ and $y$, which is at most 7 because the presence of all four edges $xv_2, xv_4, yv_1, yv_3$ would make $G$ Hamiltonian, hence $C$ would not be a longest cycle.

Finally we have to consider graphs without any cycles longer than 3. It means that each block of $G$ is $K_2$ or $K_3$. Let $f(n)$ denote the maximum number of edges in such a graph. We
clearly have \( f(1) = 0, f(2) = 1, f(3) = 3 \). Let \( B \) be an endblock of \( G \), with cut vertex \( w \). Deleting \( B - w \) from \( G \) we obtain a \( S_{3,1,1} \)-free connected graph of order \( n - |V(B)| + 1 \), where \( |V(B)| \) is 2 or 3. Hence

\[
f(n) \leq \max\{f(n - 1) + 1, f(n - 2) + 3\}.
\]

This recursion implies \( f(n) \leq \lceil 3(n - 1)/2 \rceil \) for every \( n \), completing the proof of the upper bound for \( n \geq 7 \). \( \square \)

**Theorem 3.6.** \( \text{ex}_c(n, S_{2,2,1}) = 2n - 3 \) if \( n \geq 6 \).

**Proof.** The lower bound is shown by \( K_2 + E_{n-2} \) as it has matching number 2, while \( \nu(S_{2,2,1}) = 3 \).

To obtain the upper bound on \( \text{ex}_c(n, S_{2,2,1}) \), we proceed by induction: for \( n = 6 \) every connected graph on 6 vertices and 10 edges contains \( S_{2,2,1} \) (by inspecting the table of graphs of \([8]\) on pages 222–224).

For the induction step assume that the statement of the theorem holds for graphs of at most \( n - 1 \) vertices and assume on the contrary that \( G \) is a connected graph on \( n \) vertices and \( 2n - 2 \) edges without \( S_{2,2,1} \). Here \( 2n - 2 \) suffices as otherwise if \( e(G) \geq 2n - 1 \), we can delete an edge on a cycle.

If \( \delta(G) \leq 2 \) and there is a vertex \( v \) of degree at most 2 which is not a cut-point, then we can apply induction to \( H = F - v \) to obtain \( e(G) \leq e(H) + 2 \leq 2(n - 1) - 3 + 2 = 2n - 3 \), a contradiction.

Suppose \( \delta(G) = 2 \) and every vertex of degree 2 is a cut-point. Then let \( v \) be such a cut-point with neighbors \( x \) and \( y \). Consider \( H = G - v + (xy) \). Here \( |H| = n - 1 \) and \( e(H) = 2n - 2 - 2 + 1 = 2(n - 1) - 2 + 1 \), hence by induction \( H \) contains a copy \( S \) of \( S_{2,2,1} \). If \( S \) does not use the edge \( xy \), then \( S \) is also in \( G \) — a contradiction. If \( S \) uses \( xy \) such that one of \( x \) and \( y \), say \( x \), is a leaf in \( S \), then replace \( x \) by \( v \) and the edge \( xy \) by \( vy \) to obtain a copy \( S' \) of \( S_{2,2,1} \) in \( G \) — a contradiction. Finally, if \( x \) is the edge of a 2-leg of \( S \) containing the center, say \( x \) and the leg is \( xyz \), then replace this leg by \( xy \) to obtain \( S' \) in \( G \) — a contradiction.

So we can assume \( \delta(G) \geq 3 \). If all vertices are of degree 3, then \( e(G) = 3n/2 < 2n - 2 \). If all vertices are of degree at least 4, then \( e(G) \geq 2n > 2n - 2 \), hence there exists a vertex \( y \) of degree 3 adjacent to a vertex \( x \) of degree at least 4. Let \( u, v \) be the other two neighbors of \( y \), and let \( z \neq u, v, y \) be a neighbor of \( x \). If \( u \) or \( v \) has a neighbor outside these 5 vertices, then we obtain a copy of \( S_{2,2,1} \) with center \( y \). If not and \( N(x) = \{u, v, y, z\} \), then \( z \) must have a neighbor outside these 5 vertices and we obtain a copy of \( S_{2,2,1} \) with center \( x \). Finally, if \( N(u) \cup N(v) \subseteq \{u, v, x, y, z\} \) and \( z' \) is another neighbor of \( x \), then \( d_G(z') \geq 3 \) implies that \( z' \) must have a neighbor outside these 6 vertices, and we obtain a copy of \( S_{2,2,1} \) with center \( x \). This contradiction finishes the proof. \( \square \)

**Proof of Theorem 4.** The assertion is trivial for \( n < 7 \). For larger \( n \) the split graph construction \( K_2 + E_{n-2} \) shows that \( 2n - 3 \) is a lower bound.

To derive the same as an upper bound, assume \( n > 6 \) and consider any \( D^* \)-free graph \( G \) of order \( n \) with more than \( 2n - 4 \) edges. Then, by Theorem 4.6 \( 2 \), there is a \( D = D_{2,2} \) subgraph in \( G \); let the central edge of \( D \) be \( xy \).
If some vertex not in \( D \) is adjacent to a leaf of \( D \), then a copy of \( D_{2,2} \) arises, a contradiction. More generally, there cannot exist any vertex at distance exactly 2 from \( \{ x, y \} \). By the connectivity of \( G \), it follows that every vertex of \( G \) is adjacent to at least one of \( x \) and \( y \). On this basis we partition \( V(G) - \{ x, y \} \), defining
\[
X = N(x) - N[y], \quad Y = N(y) - N[x], \quad Z = N(x) \cap N(y).
\]
Let us assume \(| Y | \geq | X |\). Due to the presence of \( D_{2,2} \) we know that \(| X | + | Z | \geq 2 \) holds. Moreover, \(| Y | \geq | X |\) with \( n \geq 7 \) implies \(| Y | + | Z | \geq 3 \). Hence there cannot be any \( X - Y \) edges, moreover \( Y \cup Z \) is an independent set, both because \( G \) is \( D_{2,2} \)-free. For the same reason, if \(| X | + | Z | > 2 \), then also \( X \cup Z \) is independent. In this case the entire \( X \cup Y \cup Z \) is independent and \( G \) cannot have more than \( 2n - 3 \) edges, yielding just the extremal split graph \( K_2 + E_{n-2} \). Otherwise, if \(| X | + | Z | = 2 \), there can be just one edge inside \( X \cup Z \), hence we have 6 edges in the \( K_4 \) subgraph induced by \( X \cup Z \cup \{ x, y \} \), and there are further \( n - 4 \) edges from \( Y \) to \( y \). These are altogether \( n + 2 \) edges only, i.e. fewer than the assumed \( 2n - 3 \). This contradiction completes the proof. \( \square \)

**Proof of Theorem 1.8** To simplify notation, let \( f(n) = ex_c(n, S_{2,2,2}) \). The lower bound for \( n \leq 7 \) is obtained by the following construction that works for all \( n \). Take a complete graph \( K_4 \) on the vertex set \( \{ v_1, v_2, v_3, v_4 \} \) and join all \( v_i \) for \( i = 5, 6, \ldots, n \) to \( v_1 \) and \( v_2 \). Equivalently, \( v_1 \) and \( v_2 \) are universal vertices, supplemented with the single edge \( v_3v_4 \). This connected graph with \( 2n - 2 \) edges does not contain \( S_{2,2,2} \) because it is not possible to delete two vertices from \( S_{2,2,2} \) to destroy all but one edges.

The argument for the upper bound applies induction on \( n \), with basic cases \( n \leq 7 \), from which only \( n = 7 \) is nontrivial. We note here that \( n = 5 \) and \( n = 6 \) are the only cases where \( 2n - 2 \) is not an upper bound on the formula given for \( f(n) \).

For \( n = 7 \) the assertion is that every connected graph \( G \) with 7 vertices and at least 13 edges contains \( S_{2,2,2} \) as a subgraph. To prove it, suppose first that \( G \) has a cut-point \( x \), and consider the vertex distribution between the components of \( G - x \). If it is (3,3) — where we unite components if there are more than two, e.g. the distribution (3,2,1) is also viewed as (3,3) — then already 9 nonadjacencies are found, hence \( G \) would have at most \( 21 - 9 = 12 \) edges, a contradiction. If the distribution is (2,4), then it forces 8 nonadjacencies, hence \( G \) must be the graph in which the two blocks incident with \( x \) are \( K_3 \) and \( K_3 \). Obviously this graph contains \( S_{2,2,2} \). If the distribution is (1,5), then \( x \) has a pendant neighbor, say \( y \), and \( G - y \) is a connected graph of order 6, having at least 12 edges. Routine inspection shows that all such graphs \( G \) contain \( S_{2,2,2} \).

Assume that \( G \) is 2-connected. If \( G \) has minimum degree 3, then \( G \) has a Hamiltonian cycle, say \( C = v_1v_2v_3v_4v_5v_6v_7 \). (More generally it is well known that a graph of order \( 2d + 1 \) and minimum degree \( d \) is non-Hamiltonian if and only if either it is the complete bipartite graph \( K_{d,d+1} \) or it has two blocks incident with a cut vertex, both blocks being \( K_{d+1} \); in our case both of them would have only 12 edges.) The presence of any long chord in \( C \), e.g. \( v_3v_6 \) immediately creates an \( S_{2,2,2} \) with center \( v_3 \) and legs \( v_3v_2v_1, v_3v_4v_5, v_3v_6v_7 \). Moreover, any three consecutive short chords, e.g. \( v_2v_4, v_3v_5, v_4v_6 \) create an \( S_{2,2,2} \) with center \( v_4 \) and legs
$v_4v_2v_1, v_4v_3v_5, v_4v_6v_7$. And now at least one of these situations holds because in general a cycle of length $n$ without three consecutive short chords and with no other chords at all can have no more than $n + 2n/3 < 2n - 2$ edges if $n \geq 7$.

Hence in the 2-connected case $G$ has minimum degree exactly 2, and if we remove a vertex $x$ of degree 2, we obtain a graph on 6 vertices with at least 11 edges. If it is $K_5$ with a pendant edge, then the pendant vertex must be adjacent to $x$ and we immediately find $S_{2,2,2}$. Otherwise there can be at most one vertex of degree 2 in $G - x$, hence it contains a $C_6$, say $v_1v_2v_3v_4v_5v_6$ (as a rather particular corollary of Pósa’s theorem). If the two neighbors of $x$ are antipodal in $C$, e.g. $v_3$ and $v_6$, we find $S_{2,2,2}$ with center $v_3$ and legs $v_3xv_6, v_3v_2v_1, v_3v_4v_5$. If the two neighbors of $x$ are consecutive in $C$, then $C$ extends to $C_7$ which we already settled. Hence we can assume that the neighbors of $x$ are $v_2$ and $v_4$. Since $C$ has at least 5 chords, some of the five chords $v_1v_3, v_1v_4, v_2v_5, v_3v_5, v_3v_6$ must be present, and each of them creates $S_{2,2,2}$ with $x$ and the edges of $C$. This completes the proof of $f(7) = 12$.

Turning now to the inductive step, assume that $n \geq 8$ and that the upper bound $2n - 2$ is valid for all smaller orders other than 5 and 6. Depending on the structure of the graph under consideration, we will apply one of the following upper bounds:

$$f(n - 1) + 2, \quad f(n - 3) + 6, \quad f(n - 6) + 12.$$  

Suppose that $G$ is an $S_{2,2,2}$-free connected graph of order $n \geq 8$, and $G$ is $S_{2,2,2}$-saturated, i.e. the insertion of any new edge inside $V(G)$ would create an $S_{2,2,2}$ subgraph. Under the latter assumption we observe the following.

**Claim 3.7.** If $x$ is a vertex of degree 2, say with neighbors $y$ and $z$, then $y z$ is also an edge of $G$.

*Proof of Claim.* Otherwise $yxz$ would be an induced path in $G$. Let then $G'$ be the graph obtained by the insertion of edge $yz$. By assumption there is an $S = S_{2,2,2}$ subgraph in $G'$, which necessarily contains the edge $yz$. If $yz$ is a leaf edge of $S$, then of course the degree-3 center of $S$ cannot be $x$, it must be another vertex $w$ adjacent to $y$ or to $z$. But then $z$ or $y$ is a leaf vertex of $S$, and replacing $yz$ with $yx$ or $zx$ we find another copy of $S_{2,2,2}$ which is a subgraph of $G$, a contradiction. The other possibility would be that $y$ or $z$ is the degree-3 vertex of $S$, and the edge $yz$ is continued with a leaf edge $zw$ or $yw$ (allowing also $w = x$). But then $x$ cannot be a mid-vertex of any leg of $S$ since $x$ does not have a neighbor other than $y$ and $z$. Hence the leg $yzw$ or $zyw$ can be replaced with $yx z$ or $zy x$, and we would again find a copy of $S_{2,2,2}$ as a subgraph of $G$. $\square$

As a consequence of Claim 3.7, if $G$ has a vertex of degree 1 or 2, then $|E(G)| \leq f(n-1)+2 \leq 2n - 2$ follows by induction, because deleting a vertex of minimum degree the graph remains connected. Hence from now on we may assume that $G$ has minimum degree at least 3.

Let $C = v_1v_2v_3v_4 \ldots v_s$ be a longest cycle in $G$. We have already seen that if $s = n$, then $|E(G)| \leq 5n/3 < 2n - 2$. Next, we observe that if $n > s \geq 5$, then $V(G) \setminus V(C)$ is an independent set. Indeed, if $xy$ is an edge outside $C$ then there is a path $P$ (possibly an edge) from $\{x, y\}$ to $C$ and in this case a copy of $S_{2,2,2}$ is easily found using edges of $C$, with two
edges from \( P \cup \{xy\} \). E.g., if \( v_3x \) is an edge, then \( S_{2,2,2} \) can have center \( v_3 \) and legs \( v_3xy, v_3v_2v_1, v_3v_4v_5 \). Thus, every vertex outside of \( C \) has at least three neighbors in \( C \). Moreover, no two of those neighbors are consecutive in \( C \), because \( C \) is longest. This immediately excludes \( s = 5 \). But also \( s > 5 \) is impossible because if e.g. \( v_2, v_4, v_6 \) are neighbors of \( x \), then an \( S_{2,2,2} \) can have center \( x \) and legs \( xv_2v_1, xv_4v_3, xv_6v_5 \).

As a consequence, investigations are reduced to \( S_{2,2,2} \)-free connected graphs with minimum degree 3 and without any cycles longer than 4. Such a graph \( G \) cannot be 2-connected (because due to Dirac’s theorem, 2-connectivity would imply the presence of a cycle longer than 5). Hence \( G \) contains at least two endblocks.

Let \( B \) be an endblock of \( G \), attached with cut-point \( w \) to the other part of \( G \). We argue that \( B \) induces \( K_4 \) in \( G \). All vertices of \( B \) except \( w \) have degree at least 3 inside \( B \), therefore \( B \) contains a 4-cycle, say \( C' = wxyz \). If there is a vertex \( u \) in \( V(B) \setminus V(C') \), then 2-connectivity of \( B \) and the exclusion of cycles longer than 4 imply that there are exactly two neighbors of \( u \) in \( C \), either \( w \) and \( y \), or \( x \) and \( z \). But then there must exist a third neighbor \( v \) of \( u \) not in \( C \), and \( v \) also has two neighbors in \( C \); and then a cycle longer than 4 would occur. Thus \( B \) is a \( K_4 \) indeed.

Now we are in a position to complete the proof of the theorem by induction on \( n \). Consider any maximal \( S_{2,2,2} \)-free connected graph \( G \) of order \( n > 7 \) that has at least \( 2n - 2 \) edges. If \( G \) has a vertex of degree at most 2, then apply the upper bound \( f(n-1) + 2 \).

If \( G \) has minimum degree at least 3, we know that \( G \) is not 2-connected. Then:

If \( n = 8 \) or \( n = 9 \), remove all the 6 non-cutting vertices of two \( K_4 \) endblocks of \( G \) and apply the upper bound \( f(n-6) + 12 \). This yields \( |E(G)| \leq 13 \) for \( n = 8 \) and \( |E(G)| \leq 15 \) for \( n = 9 \), both are smaller than \( 2n - 2 \).

If \( n \geq 10 \), remove the 3 non-cutting vertices of a \( K_4 \) endblock of \( G \) and apply the upper bound \( f(n-3) + 6 \). This yields \( |E(G)| \leq 2n - 2 \). \( \square \)

**Remark 3.8.** The extremal graphs are not unique if \( n \geq 7 \). In the graph constructed at the beginning of the proof we can remove three vertices of degree 2 and attach a block \( K_4 \) to one of the two high-degree vertices. As another alternative for \( n \geq 10 \), we can remove six vertices of degree 2 and attach two blocks isomorphic to \( K_4 \), one block to each high-degree vertex. A further extremal graph of order 7 can be obtained from \( K_5 \) by attaching two pendant edges to a vertex of \( K_5 \).

**Proof of Theorem 3.9.** A lower bound for \( n \geq 7 \) is the split graph \( K_2 + E_{n-2} \) with \( 2n - 3 \) edges which does not even contain \( S_{2,2,1} \) and hence \( S_{3,2,1} \) cannot be a subgraph either.

The proof of the upper bound proceeds by induction on \( n \). The base case \( n = 7 \) is left to the Reader.

Assume \( G \) is a minimum connected counterexample with \( n \geq 8 \) vertices and has at least \( 2n - 2 \) edges but no copy of \( S_{3,2,1} \).

If \( G \) contains a vertex \( v \) of degree at most 2 such that \( H = G - v \) is connected, then, by minimality, \( e(H) \leq 2(n-1) - 3 \) hence \( 2n - 2 \leq e(G) \leq e(H) + 2 \leq 2n - 3 \), a contradiction.
Next, assume \( v \) is a cut-point with neighbors \( x \) and \( y \). Consider the graph \( H \) that we obtain from \( G \) by deleting \( v \) and adding the edge \( xy \). We will show that if \( H \) contains \( S_{3,2,1} \) then so does \( G \). Let \( A \) be the component containing \( x \) and \( B \) the component containing \( y \). By symmetry we may assume that if \( H \) contains a copy \( S \) of \( S_{3,2,1} \), then its center is in \( A \) and so \( B \) can contain vertices of at most one leg of \( S \). We consider cases according to the number of vertices in \( S \cap B \). If \( A \) contains \( S_{3,2,1} \) completely, then so does \( G \). If \( A \) contains all of \( S_{3,2,1} \) except for a leaf played by \( y \), then the same copy with \( v \) replacing \( y \) is contained in \( G \).

If \( S \cap B = \{y, w\} \), then the leg of \( S \) ending \( x - y - w \) can be replaced in \( G \) with \( x - v - y \) to obtain a copy \( S' \) of \( S_{3,2,1} \). If \( S \cap B = \{y, w, z\} \), then the leg of \( S \) ending \( x - y - w - z \) can be replaced in \( G \) with \( x - v - y - w \) to obtain a copy \( S' \) of \( S_{3,2,1} \).

So, as proved, \( H \) must be \( S_{3,2,1} \)-free, hence \( 2n - 2 \leq e(G) \leq e(H) + 1 \leq 2(n - 1) - 3 + 1 \leq 2n - 4 \), a contradiction.

Therefore, from now on we may assume \( \delta(G) \geq 3 \). By Theorem 1.6 (4), we know that \( G \) contains a copy \( S \) of \( S_{2,2,1} \). Let \( v \) be the center of \( S \) with legs \( v - u, v - x - y \), and \( v - a - b \). If \( y \) or \( b \) has a neighbor not in \( S \), then \( G \) contains a copy of \( S_{3,2,1} \) — a contradiction.

Suppose \( x \) (or \( a \)) has a neighbor \( z \) not in \( S \). Then \( z \) cannot be adjacent to any of \( v, y, a, b \) as a copy of \( S_{3,2,1} \) would appear. Also, \( z \) cannot be adjacent to any vertex outside \( S \) as again a copy of \( S_{3,2,1} \) would appear in \( G \). By \( \delta(G) \geq 3 \), \( z \) must be adjacent to \( u, x \), and \( a \), but then a copy of \( S_{3,2,1} \) (this time with center \( z \)) would appear in \( G \).

We have shown so far that \( x, y, a, b \) cannot have neighbors outside \( S \).

If \( u \) has at least two neighbors \( z \) and \( w \) outside \( S \), then they cannot be adjacent (it would create the leg \( v - u - z - w \) of a copy of \( S_{3,2,1} \)) and none of them can have a neighbor outside \( S \) as a copy of \( S_{3,2,1} \) would appear in \( G \). As shown above, they cannot be adjacent to any of \( x, y, a, b \) hence they have degree at most 2 (with neighbors \( u \) and possibly \( v \)) contradicting \( \delta(G) \geq 3 \).

If \( u \) has just one neighbor, say \( z \) outside \( S \), then \( z \) cannot have a neighbor outside \( S \) as a copy of \( S_{3,2,1} \) would appear, and as before, \( z \) cannot be adjacent to any of \( x, y, a, b \) hence \( z \) can be adjacent to at most \( u \) and \( v \) but then \( d_G(z) \leq 2 \) contradicts \( \delta(G) \geq 3 \).

So the only vertex of \( S \) that can have further neighbors outside \( S \) is \( v \). We claim that there cannot exist a path \( v - w - z \) with \( w, z \notin S \). Indeed, if \( w, z \) existed, then any of the edges \( ax, ay \) would create a copy of \( S_{3,2,1} \) with center \( a \). Similarly, any of the edges \( xa, xb \) would create a copy of \( S_{3,2,1} \) with center \( b \). But then \( \delta(G) \geq 3 \) implies the presence of \( ua \) and \( ux \) in \( G \) creating a copy of \( S_{3,2,1} \) with center \( u \). Therefore all vertices outside \( S \) must have degree 1, which case has already been dealt with. This finishes the proof of the induction step. □

**Proof of Theorem 1.10.** It is enough to prove that if \( G \) is a connected \( n \)-vertex graph with \( \Delta(G) \geq \Delta(T) \), then \( G \) contains \( T \) or \( e(G) \leq \lceil \frac{(\Delta(T) - 1)n}{2} \rceil \). So fix a vertex \( v \) with \( d_G(v) = \Delta(G) \geq \Delta(T) \) and consider the partition \( \{v\}, N(v) \), \( X := V(G) \setminus N[v] \).

If \( X \) contains an edge \( xy \), then by connectivity of \( G \), there must exist a path (maybe a single edge) from \( xy \) to \( N(v) \) and we find a copy of \( T \) in \( G \). So we may assume that \( X \) is independent, and thus by connectivity of \( G \), every \( x \in X \) is adjacent to at least one \( u \in N(v) \).
Case I: \( d_G(v) = \Delta(G) > \Delta(T) \).

Then any \( x \in X \) is adjacent to exactly one vertex \( u \in N(v) \) as if \( xu, xu' \) are edges in \( G \), then \( xu' \) can form the long leg of a copy of \( T \) with center \( v \) and other neighbors of \( v \) complete this copy of \( T \). So \( d_G(x) = 1 \) for all \( x \in X \). Let \( u, u' \in N(v) \) be two vertices such that at least one of them has a neighbor in \( X \). Then again if \( uu' \) is an edge, we find a copy of \( T \). So if \( U \subseteq N(v) \) is the set of neighbors of \( v \) that are adjacent to a vertex in \( X \) and \( U' = N(v) \setminus U \), then \( e(G) \leq (|\{v\} \cup U \cup X| - 1) + e(U') \). If \( |U'| \leq \Delta(T) + 1 \), then \( e(U') \leq (\Delta(T)+1) \) and so \( e(G) \leq n - 1 + (\Delta(T)+1) \leq \left\lfloor \frac{(\Delta(T)-1)n}{2} \right\rfloor \) as \( \Delta(T) - 1 \geq 3 \). Finally, if \( |U'| \geq \Delta(T) + 2 \), then either \( G[U'] \) is a (partial) matching and thus \( e(G) \leq 1 + |U| + |X| - 1 + \frac{3|U'|}{2} \leq \frac{3(n-1)}{2} \leq \left\lfloor \frac{(\Delta(T)-1)n}{2} \right\rfloor \) (here we use \( \Delta(T) \geq 4 \)) or \( G[U'] \) contains a path on 3 vertices, and then by \( |U'| \geq \Delta(T) + 2 \) we find a copy of \( T \) in \( G \).

Case II: \( d_G(v) = \Delta(G) = \Delta(T) \).

As \( X \) is independent, we have \( e(G) \leq (\Delta(G) + 1)\Delta(G) = (\Delta(T) + 1)\Delta(T) = O(1) \). \( \square \)

4. Concluding remarks

Theorem 1.5 gave upper and lower bounds on \( \gamma \). If the lower bound of either (1) or (3) of Theorem 3.2 turned out to be (asymptotically) sharp (which we believe to be the case) for \( a = (1/2 - \varepsilon)k \) or \( a = (1/2 + \varepsilon)k \), then the upper bound on \( \gamma \) would improve from 2/3 to 1/2. Note that a special case of Theorem 1.10 yields \( \text{ex}_c(n, S_{3,1,1,1}) = \left\lfloor \frac{(\Delta(S_{3,1,1,1})-1)n}{2} \right\rfloor \), so a small case when \( a = \lceil k/2 \rceil \). We have no evidence to believe that the lower bound of 1/3 on \( \gamma \) is best possible.

In Proposition 1.3, we enumerated several graph parameters based on which we could define general constructions avoiding trees \( T \) for which these parameters have small value. It would be nice to add other parameters to this list, and would be wonderful to prove that it is enough to consider a finite set of parameters to determine the asymptotics of \( \text{ex}_c(n, T) \) for all trees \( T \). Of particular interest is the characterization of those trees for which \( \text{ex}(n, T) - c(T) \leq \text{ex}_c(n, T) \leq \text{ex}(n, T) \) holds for some constant \( c(T) \).

As for special tree classes, one such class that could give some insight is the set of spiders with all legs of at most 2 vertices. For the spider \( S = S_{2,2,\ldots,2,1,1,\ldots,1} \) with \( t \) legs of two vertices and \( s \) legs consisting of a single vertex, we have \( |S| = 2t + s + 1 \), and

- \( \nu(T) = t + 1 \) if \( s > 0 \),
- \( \Delta(T) = t + s \),
- \( m_2(T) = 4 \) if \( t \geq 2 \).

The construction of Proposition 1.6 (3) based on maximum degree outperforms the one based on the matching number in Proposition 1.6 (4) if \( s > t \). But the one based on \( m_2 \) in Proposition 1.6 (8) is better than both previous ones once \( s \geq 5 \) and \( t \geq 2 \). It would be interesting to see whether these constructions achieve the asymptotics of \( \text{ex}_c(n, S) \).
Classical Turán numbers are monotone with two respects: Firstly, if $H$ is a subgraph of $F$ then $\text{ex}(n, H) \leq \text{ex}(n, F)$. This inequality is preserved for the connected Turán number $\text{ex}_c(n, F)$ (excluding the small “undefined” cases $K_2$ and $P_3$). Secondly, if $m < n$, then $\text{ex}(m, F) \leq \text{ex}(n, F)$. This property is not necessarily preserved by connected Turán numbers for small values of $n$ with respect to $|T|$. There are several examples given by our results, of the following type: $\text{ex}_c(|T| - 1, T) = \binom{|T| - 1}{2} > \text{ex}_c(|T|, T)$; see e.g. $T = S_{3,2,1}$.

**Problem 4.1.** Is it true that there exists a threshold $n_0(F)$ such that $\text{ex}_c(m, F) \leq \text{ex}_c(n, F)$ holds whenever $n_0(F) \leq m < n$?
