(Dated: June 29, 2018)

We perform an Internal Robustness analysis (iR) to a compilation of the most recent \( f \sigma_8(z) \) data, using the framework of Ref. \[1\]. The method analyzes combinations of subsets in the dataset in a Bayesian model comparison way, potentially finding outliers, subsets of data affected by systematics or new physics. In order to validate our analysis and assess its sensitivity we performed several cross-checks, for example by removing some of the data or by adding artificially contaminated points, while we also generated mock datasets in order to estimate confidence regions of the iR. Applying this methodology, we found no anomalous behavior in the \( f \sigma_8(z) \) dataset, thus validating its internal robustness.

Keywords: cosmology, dark energy, model comparison

I. INTRODUCTION

During the last twenty years a plethora of observations suggests that the Universe is undergoing a phase of accelerated expansion at late times. In order to explain this phenomenon, the concept of attractive gravity had to be revised either by introducing a new form of matter dubbed dark energy, see Ref. \[2\] for a review, or by altering explicitly the laws of gravity \[3\]. However, the simplest way to account for a phase of accelerated expansion of the Universe within the framework of Friedmann-Lemaître-Robertson-Walker (FLRW) cosmology is to simply introduce a cosmological constant \( \Lambda \). While this model gives rise to severe coincidence and fine-tuning problems, current cosmological observations are still compatible with a Universe that is filled by dark energy component that has the same characteristics of the cosmological constant \[4\].

Nonetheless, these cosmological observations are not accurate enough at the moment to either constrain any potential time evolution of the cosmological constant, which might lead dark energy to cluster, or any modifications of gravity. Despite the fact that the two aforementioned classes of theories can in principle be arbitrarily similar \[5\] \[6\], it is still necessary to be able to discriminate between the currently available models.

Future surveys such as Euclid \[7\] and LSST \[8\], both of which will gather orders of magnitude more data than current surveys, it would be interesting to constrain the dynamical features of gravity and test our assumptions. One way to do this is via the growth of matter density perturbations \( \delta_m = \delta \rho_m / \rho_m \) and its logarithmic derivative the growth rate \( f = d \ln \delta_m / d \ln a \). In practice, most of the growth rate measurements are made via the peculiar velocities obtained from Redshift Space Distortions (RSD) measurements \[9\] coming from galaxy redshift surveys. In general, these surveys measure the perturbations of the galaxy density \( \delta_g \), which can be related to (dark) matter perturbations through the bias \( b \) via \( \delta_g = b \delta_m \). Thus, initial growth rate measurements measured the growth rate \( f \) divided by the bias factor \( b \) leading to the parameter \( \beta \equiv f / b \). This parameter is very sensitive to the value of the bias which can vary in the range \( b \in [1, 3] \), thus making difficult to combine \( \beta \) from different surveys and as a result leading to unreliable datasets of \( \beta(z) \).

As a result, a more reliable parameter was sought and this was found in the combination \( f(z) \sigma_8(z) \equiv f \sigma_8(z) \), which can be shown to be independent of the bias, and can be measured either via weak lensing or RSD observations. Still, the current measurements of \( f \sigma_8(z) \) (presented in later sections) come from a plethora of different surveys with different assumptions and systematics, thus an approach to study the statistical properties and robustness of the data is imperative.

One such approach is the so-called “Internal Robustness”, pioneered in Ref. \[1\]. This is a fully Bayesian approach which is not only sensitive to the local minimum like a standard \( \chi^2 \) comparison, but also to the entire likelihood and can in principle detect the presence of systematics in the dataset. The main goal of this approach is to identify systematic-contaminated data-points, which can then be further analysed and potentially excluded if they cannot be corrected.

In this paper we present an application of the “Internal Robustness” approach to the currently available growth-rate data in the form of \( f \sigma_8(z) \) with the aim to examine the dataset for systematics and outlier points in a fully automated manner. The layout of our manuscript is as follows: in Sec. \[11\] we provide the basic elements of FLRW cosmology related to our models, in Sec. \[11\] we briefly review the “Internal Robustness” method and its appli-
cation to the growth data, while in Sec. IV we provide the compilation of growth data used in our analysis and finally, we discuss our results in Sec. V.

II. BASIC EQUATIONS

In this section we present the basic equations required in our analysis. We begin with the Hubble parameter in a flat $\Lambda$CDM universe (with a constant equation of state parameter for dark energy $w = -1$), given by

$$H(a)^2 = H_0^2 \left[ \Omega_{m,0} a^{-3} + (1 - \Omega_{m,0}) \right],$$

where $H_0$ is the Hubble constant, and $\Omega_{m,0}$ is the present day value of the matter density parameter and $a$ is the scale factor. The matter density can then also be expressed as a function of the scale factor:

$$\Omega_m(a) = \frac{\Omega_{m,0} a^{-3}}{H(a)^2 / H_0^2}.$$

Under the assumption of flat $\Lambda$CDM model, the angular diameter distance takes an analytical expression, given by:

$$d_A(a) = \frac{H_0}{c} \sqrt{\Omega_{m,0}} a = 2F_1 \left[ \frac{1}{2}, \frac{1}{6} : 1 + \frac{1}{6} ; \left( 1 - \frac{1}{\Omega_{m,0}} \right) \right] - \sqrt{a} \cdot 2F_1 \left[ \frac{1}{2}, \frac{1}{6} : 1 + \frac{1}{6} ; \left( 1 - \frac{1}{\Omega_m(a)} \right) \right],$$

where $2F_1$ is the hypergeometric function. The matter density perturbations in Fourier space $\delta_m(a,k)$ depend on the underlying cosmological model; for the $\Lambda$CDM scenario, the linear matter perturbations grow according to

$$\delta''_m(a) + \left( \frac{3}{a} + \frac{H'(a)}{H(a)} \right) \delta'_m(a) - \frac{3}{2} \Omega_m(a) \frac{a^2}{\Omega_{m,0}} \delta_m(a) = 0.$$

The equation above has an analytical solution for the growing mode, given by [10–12]

$$\delta_m(a) = a \cdot 2F_1 \left[ \frac{1}{3}, 1 ; \frac{11}{6} ; a^3 \left( 1 - \frac{1}{\Omega_{m,0}} \right) \right].$$

Note that the dependence on the wave number $k$ disappears because of the assumption of small scales approximation.

We define the growth rate $f$ and the root mean square (RMS) normalization of the matter power spectrum $\sigma_s$ as:

$$f(a) = \frac{d \log \delta_m}{d \log a},$$

$$\sigma_s(a) = \sigma_{s,0} \frac{\delta_m(a)}{\delta_m(1)}.$$

As already mentioned in Sec. II, a more robust and reliable quantity that is measured by redshift surveys is the combination of the growth rate $f(a)$ and the RMS $\sigma_s(a)$:

$$f\sigma_s(a) = a \frac{\delta_m(a)}{\delta_m(1)} \sigma_{s,0}.$$

Equation (8) will be our key quantity, which will be tested with the most recent data available in the following sections.

III. FORMALISM

Here we report the basic equations that will be used to perform our analysis and we refer to [1] for the details on the derivation of the internal robustness. The statistical definition of the Bayesian evidence is

$$E(x|M) = \int L(x|\theta^M) \pi(\theta^M) d\theta^M,$$

where $x = (x_1, x_2, ..., x_N)$ are the $N$ random data, $\theta^M = (\theta_1, \theta_2, ..., \theta_n)$ are the $n$ theoretical parameters of the model $M$. The likelihood function is $L(x|\theta^M)$, while the prior probability of the parameters of the model is $\pi(\theta^M)$. By the help of the Bayes’ theorem we can find the posterior probability $P(M|x)$ of having a model $M$ given the data

$$P(M|x) = E(x|M) \frac{\pi(M)}{E(x)}.$$

By using the last equation, we can compare two different models by considering the ratio of their probabilities:

$$\frac{P(M_1|x)}{P(M_2|x)} = B_{12} \frac{\pi(M_1)}{\pi(M_2)};$$

with the Bayes factor defined as

$$B_{12} = \frac{E(x|M_1)}{E(x|M_2)}.$$
Finally, we can define the internal robustness as

\[ iR_{12} = \log B_{12} = \log \left( \frac{\mathcal{E}(x | M_1)}{\mathcal{E}(x_1 | M_1) \mathcal{E}(x_2 | M_2)} \right). \]  

(14)

This approach allows us to detect if a subset of the data follows another cosmological model or if a specific survey is affected by systematics and hence altering the measurement itself.

However, the assumption of having two different models is not strictly mandatory and we will choose the same cosmological model for both subsets. In this work we will set the cosmological model to be \( \Lambda \)CDM and the parameters for both subsets to \( \theta = (\Omega_{m,0}, \sigma_8) \). Hereinafter, we drop the \( M \) superscript and the 1, 2 subscripts, since we only consider one cosmological model.

Our analysis invokes priors on the parameters, for that we choose a flat prior in the \([0, 1]\) range for \( \Omega_{m,0} \) in order to allow for all physical values possible for the matter density. On the other hand, the choice of a prior for \( \sigma_8 \) is less evident; since the prior directly affects the evidence value, so we are going to consider three priors for \( \sigma_8 \), to assess the impact of the prior selection on the internal robustness. We choose the following three cases:

- **Narrow flat prior**: this is a typical flat prior in the range \([0.3, 1.5]\).

- **Broad flat prior**: this is a flat prior in the range \([0, 10]\), which allows for high values of \( \sigma_8 \).

- **Gaussian prior**: the third prior to consider is a Gaussian distribution centered on 0.8150, with a standard deviation of 0.0087, based on the Planck 2015 results (TT,TE,EE+lowP+lensing [4]).

It is clear that we only allow for positive values of \( \sigma_8 \) in order to remain physical.

The data considered are \( f \sigma_8(z) \) measurements (with \( z = -1 + 1/a \) being the redshift of the measurement), and we assume a Gaussian likelihood for the data with a covariance matrix \( \mathcal{C} \). We represent the observed data in different redshifts as \( \mathbf{m} = (m(z_1), \ldots, m(z_n)) \) and its theoretical prediction as \( \mathbf{\mu}(\theta) = (\mu(z_1), \ldots, \mu(z_n)) \), which depends on the cosmological model and parameters. We also take into account the redshift correction of [13], which features a correction factor of

\[ \text{fac}(z) = \frac{H(z')}{H_{\text{ref}, i}(z')} \left[ \frac{dA_i(z')}{dA_0(z')} \right]. \]

(15)

with the label ref, \( i \) stating that the cosmology considered is the reference cosmology used on the corresponding data point on redshift \( z' \). Hence, the corrected theoretical prediction is

\[ \mu_i = \frac{\mu_i}{\text{fac}(z')} . \]

(16)

We are now in the position to define the data vector with the corresponding modification:

\[ \mathbf{x} = \mathbf{m} - \mathbf{\mu}_c . \]

(17)

Then, the chi-squared is

\[ \chi^2 = \mathbf{x}^T \mathbf{C}^{-1} \mathbf{x} , \]

(18)

which is related to the likelihood via \( L = e^{-\chi^2/2}/\sqrt{(2\pi)^n|\mathbf{C}|} \).

To speed up the computations, we note that the \( \sigma_{8,0} \) parameter can be marginalised theoretically [14][15]. We rewrite the \( \chi^2 \):

\[ \chi^2 = \mathbf{m}^T \mathbf{C}^{-1} \mathbf{m} - 2\mathbf{m}^T \mathbf{C}^{-1} \mathbf{\mu}_c + \mathbf{\mu}_c^T \mathbf{C}^{-1} \mathbf{\mu}_c . \]

(19)

The corrected theoretical prediction marginalised over \( \sigma_{8,0} \) will be \( \mathbf{\nu} = \mathbf{\mu}/\sigma_{8,0} \). Then, the \( \chi^2 \) can be rewritten as

\[ \chi^2 = \xi_{\mu\mu} - 2\xi_{\mu\nu} + \xi_{\nu\nu} \sigma_{8,0}^2 , \]

(20)

where the single terms are:

\[ \xi_{\mu\mu} = \mathbf{m}^T \mathbf{C}^{-1} \mathbf{m} , \]

\[ \xi_{\mu\nu} = \mathbf{m}^T \mathbf{C}^{-1} \mathbf{\nu} , \]

\[ \xi_{\nu\nu} = \mathbf{\nu}^T \mathbf{C}^{-1} \mathbf{\nu} . \]

(21)

The posterior probability distribution marginalised over \( \sigma_{8,0} \) is

\[ \mathcal{P}(\Omega_{m,0}) = \int L(\Omega_{m,0}, \sigma_{8,0}) \pi(\Omega_{m,0}, \sigma_{8,0}) d\sigma_{8,0} . \]

(22)

We now consider two cases for the prior probability on \( \sigma_{8,0} \): a flat prior between \([a, b]\) and a Gaussian prior with mean \( s \) and variance \( \epsilon^2 \). Let us start by considering the flat prior case. The integration of the posterior is:

\[ \mathcal{P}_f(\Omega_{m,0}) = \frac{1}{(b - a)\sqrt{2\pi}|\mathbf{C}|} \int_a^b e^{-\chi^2/2} d\sigma_{8,0} = \frac{1}{(b - a)\sqrt{2\pi}|\mathbf{C}|} \exp \left( -\frac{1}{2} \left[ \xi_{\mu\mu} - \xi_{\mu\nu} \xi_{\nu\nu} \right] \right) I_f , \]

(23)

where the quantity \( I_f \) is:

\[ I_f = \int_a^b e^{-\xi_{\nu\nu}(\xi_{\mu\nu}/\xi_{\nu\nu} - s)^2} d\sigma_{8,0} = \left[ \sqrt{\frac{\pi}{2\xi_{\nu\nu}}} \exp \left( -\frac{\xi_{\nu\nu}^2}{2\sigma^2} \right) \right]_a^b . \]

(24)

For the Gaussian prior case we find, by discarding negative values:

\[ \pi_g(\sigma_{8,0}) = \frac{e^{-\frac{1}{2}(s - \sigma_{8,0})^2/\epsilon^2}}{\int_s^\infty e^{-\frac{1}{2}(s - \sigma_{8,0})^2/\epsilon^2} d\sigma_{8,0}} e^{-\frac{1}{2}(s - \sigma_{8,0})^2/\epsilon^2} \]

\[ = \sqrt{\pi\epsilon^2/2 \left[ 1 + \text{erf}(s/\sqrt{2\epsilon^2}) \right]} \]

\[ = A_g e^{-\frac{1}{2}(s - \sigma_{8,0})^2/\epsilon^2} , \]

(25)
where we implicitly defined the normalization constant $A_g$.

The posterior probability distribution function then reads:

$$\mathcal{P}_g(\Omega_{m, 0}) = \frac{A_g}{\sqrt{2\pi}^{n}[C]} \int_0^\infty e^{-[x^2 + (s - \sigma_{8, 0})^2]/2} \, d\sigma_{8, 0}$$

$$= \frac{A_g}{\sqrt{2\pi}^{n}[C]} \exp \left(-\frac{1}{2} \left[\xi_{mm} - \frac{\xi_{mm}}{\xi_{\nu \nu}}\right]\right) I_g,$$  \hspace{1cm} (26)

where $I_g$ is equal to:

$$I_g = \int_0^\infty e^{-\frac{\pi \epsilon^2}{2(\epsilon^2 \xi_{\nu \nu} + 1)}} \exp \left(-\frac{(\xi_{mm} - \xi_{\nu \nu})^2}{2\epsilon^2 \xi_{\nu \nu} (\epsilon^2 \xi_{\nu \nu} + 1)}\right) \left[1 + \text{erf}\left(\frac{\xi_{mm} \epsilon^2 + s}{\epsilon \sqrt{2(\epsilon^2 \xi_{\nu \nu} + 1)}}\right)\right].$$ \hspace{1cm} (27)

which is the multiplication of the exponentials of two Gaussians, which is also the exponential part of a Gaussian distribution.

### IV. DATA CONSIDERATIONS

#### A. The Dataset

The growth rate dataset is based on the Gold-2017 compilation from $[13]$, consisting of 18 independent measurements of $f\sigma_8(z)$, obtained from redshift space distortion measurements from a variety of surveys. Among these surveys, it is important to note that the three WiggleZ $[16]$ measurements are correlated, and their covariance matrix is

$$C_{\text{WiggleZ}} = 10^{-3} \begin{pmatrix} 6.400 & 2.570 & 0.000 \\ 2.570 & 3.969 & 2.540 \\ 0.000 & 2.540 & 5.184 \end{pmatrix}. \hspace{1cm} (28)$$

In addition to the Gold-2017 compilation, we update it with 4 recent measurements from $[17]$. These points have a covariance matrix given by

$$C_{\text{SDSS-IV}} = 10^{-2} \begin{pmatrix} 3.098 & 0.892 & 0.329 & -0.021 \\ 0.892 & 0.980 & 0.436 & 0.076 \\ 0.329 & 0.436 & 0.490 & 0.350 \\ -0.021 & 0.076 & 0.350 & 1.124 \end{pmatrix}. \hspace{1cm} (29)$$

Our final dataset will be constituted of $N = 22$ data points, shown in Table I, the possible combinations of subsets from the them is $2^{N-1} - 1 = 2097151$, and we analyze all of the subsets$^1$. The analysis is possible thanks primarily to the marginalization over $\sigma_{8,0}$, as shown in Sec. III.

#### B. Mock Data

An important feature of this work is the comparison of confidence regions for the probability distributions of the internal robustness (iR-PDF). To obtain the confidence regions, we generate mock datasets based on the form

$$f\sigma_8^{\text{mock}}(z_i) = f\sigma_8(z_i | \theta^{\text{bestfit}}) + \mathcal{N}^{\text{random}},$$ \hspace{1cm} (30)

meaning that the mock growth rate data is generated from the best fit parameters $\theta^{\text{bestfit}}$, which are obtained using the complete dataset and minimizing the posterior probability (which takes the prior into account). The $\mathcal{N}^{\text{random}}$ term is evaluated by assuming a Gaussian noise

---

$^1$ Note that we do not count the combination of the full dataset with the empty set $\emptyset$.

FIG. 1: Violin plots of the internal robustness distributions, for each of the smaller subset sizes of each partition. We employed the narrow flat prior (upper panel), broad flat prior (medium panel) and Gaussian prior (lower panel). The white dots are the mean value of the internal robustness, the bold black line is the $1\sigma$ region and the thinner black line is the $2\sigma$ region.

with zero mean and standard deviation equal to those given by the data $\sigma_{f,8}(z_i)$.

The main reason of comparing the results obtained by using the data and the mock catalogues is to compare directly the iR-PDF to the confidence regions. If the iR-PDF from the data falls off the confidence regions, then we can state that either the data set is not internally robust, meaning that the dataset could be affected by systematics, or that a better physical model is required in order to betterdescribe the data. In other words, the mock data confidence regions portrait acceptable offset levels from the best fit cosmology obtained from the complete dataset.

For each choice of the prior on $\sigma_{8,0}$, we generate 1000 mock datasets. Then, we sample each one of these datasets into 14000 subset combinations, distributed as follows: 2000 samples for subsets in which the smaller subset size (hereinafter SSS) is 11, another 2000 for subsets with SSS=10, and so on, until SSS=4. We stop at SSS=4 because the number of samples would be larger than the available combinations. As mentioned, the goal is to explore different subset sizes in an equal manner, with the further consideration that, for larger SSS value, we have more possible combinations.

As an ultimate test, we produced mock datasets based on the Planck 2015 best fit parameters [4], for which the parameters are $\Omega_{m,0} = 0.3121$ and $\sigma_{8,0} = 0.815$. The idea behind this is to check whether the tension on measurements of $\sigma_{8,0}$ between Cosmic Microwave Background (CMB) surveys like Planck and galaxy clustering surveys, see Refs. [13, 31–38], could be due to inconsistencies in the data themselves.

C. Cross-Checks

In order to ensure that the method is stable and sensitive to the dataset, we decided to opt for two extra cross-checks on our analysis. In brief, the cross-checks have been done using the narrow flat prior only, where we expect the method to be more sensitive to the final results. The cross-checks are:

- **Data removal**: we select one of the combinations with lowest internal robustness and SSS. Then, we remove the data points corresponding to the
FIG. 2: Internal Robustness PDF and confidence regions from mock data based on the best fit cosmology, using each prior. They are: narrow flat prior (upper panel), broad flat prior (medium panel) and Gaussian prior (lower panel).

FIG. 3: Same as Fig. 2 but the base parameters for the mock data are from Planck 2015. Priors used: narrow flat prior (upper panel), broad flat prior (medium panel) and Gaussian prior (lower panel).

smaller subset, and evaluate again the complete internal robustness analysis with the new dataset. Clearly this procedure forces us to generate a new mock dataset with its own best fit. The SSS value will now range from SSS=4 to the maximum SSS possible. In order to be consistent with the number of points, each SSS will be constituted of 2000 sample subsets.

- **Data contamination**: we deliberately choose to contaminate the first data point of the dataset in order to have a worse iR-PDF. This contamination has been implemented by moving the data point by $5\sigma$ away from its actual value. In other words, the new first point is constructed as

$$f_{\sigma_{\text{cont}}}^{z_1} = f_{\sigma_{z_1}} + 5\sigma_{f_{\sigma_{z_1}}}.$$  \hspace{1cm} (31)

By moving one of the point by $5\sigma$ away from its actual position, we expect the iR-PDF to be affected and fall off the confidence regions, clearly the mean iR has to decrease.
V. RESULTS AND DISCUSSION

The first results are the complete inspection of the dataset, comprising all the possible subset combinations. In Fig. 1 we show the iR-PDF in the form of violin plots, arranged by the smaller subset size (SSS) of each subset combination. The three figures differ by the prior used.

From Fig. 1 we can see that the internal robustness increases with the SSS. This result was somehow expected as larger data subsets are less prone to manifest outliers, if the data is free of systematic effects. We also see that the broad prior (middle panel in Fig. 1) has much larger iR than the narrow prior (upper panel in Fig. 1). The difference in the iR value is of the order two regardless of the SSS considered. However, the shape of the distributions changes for SSS<3. We can also see that for the Gaussian prior, the distributions are more stretched for small SSS (SSS<3) and more clumped up for medium and larger SSS.

In Fig. 2 we show the confidence regions of the mock datasets, as reported in Sec. IV, along with the iR-PDF of the corresponding prior. The dataset black lines were obtained from samples that were equal in size in each SSS as the mock data. We observe that, with the 3 types of prior, the data iR-PDF is within the confidence levels obtained in all the ranges of the internal robustness. This validates the dataset, discarding systematic contamination and any other irregularities detectable within the iR formalism.

In Fig. 3 we have plot the confidence regions with the Planck-based cosmology. We see that the confidence regions are nearly identical to those of Fig. 2, with the exception of the Gaussian prior case, where the iR-PDF gets closer to the 1σ region with the Planck-based cosmology mock data. We recall that the Gaussian prior was also chosen based on the Planck 2015 results, so this result is not controversial, although it was not automatically expected, unless we consider the prior to be more constraining than the likelihood alone.

A. Cross-checks results

As mentioned in the previous section, we decided to make a cross-check analysis to ensure that both method and dataset gave sensible results. The first check consisted of removing data points from the subset that gave the lowest robustness. In our analysis we found that the lowest SSS that gave a negative lowest robustness was constituted of 2 points (hence SSS=2) and the data points falling into this subset were the second and sixth data in the table I. We decided to name this subset ‘r26’.

Our second cross-check was to take the first data point and move 5 σs away from its actual position. The new dataset is denominated ‘c1’. In Fig. 4 we show the iR-PDFs for the cross-check datasets. We can see from the figure that, for the ‘r26’ dataset, the iR for SSS>6 has a higher minimum but the maximum iR is lower, as well as the mean iR values are smaller with respect to the full dataset. This is probably due to, when improving a dataset by adding robust points, the iR is expected to

---

2 There is no particular reason of choosing the first point. Since the dataset is statistically robust, we are allowed to take randomly any point on the list.
FIG. 5: Same as Fig. 2, but considering the ‘r26’ dataset (upper panel) and the ‘s1’ dataset (lower panel), both with a narrow flat prior. The mock data used to generate the confidence regions from the upper panel come from the best fit of the ‘r26’ dataset, while the ones for the lower panel are from the original dataset.

increase. On the other hand, the improvement in the minimum iR indeed comes from choosing to remove the points with lower iR on the original dataset.

For the second cross-check, i.e. the contamination of one datapoint, we can immediately that the internal robustness method detects the inconsistency caused by the contaminated datapoint, by exhibiting a bimodal shape and a decrease of the iR value when we increase the SSS. These are two features that are not proper of a robust dataset.

Finally, in Fig. 5 we show the confidence regions for the cross-check datasets. We can see that the confidence regions for the removal cross-check do not fully contain the iR-PDF. The reason is that, by removing some of the data points, the iR for lower SSS is more affected than those with a higher SSS. This is clear if we consider that the effect of dropping data points are more significant for a small dataset rather than a large one, assuming they have the similar weights. The anomaly in the iR-PDF for low SSS can be interpreted as the result of an artificial forcing to avoid small iR values.

For the ‘c1’ dataset we clearly see that the deviation from the confidence regions from the mock data confirms the efficacy of the methodology presented.

VI. CONCLUSIONS

In this paper we implemented the “Internal Robustness” of Ref. [1] to the currently available growth-rate data in the form of $f_{\sigma_8}(z)$ shown in Table I, with the aim to examine the dataset for systematics and outlier points in a fully automated manner. The “Internal Robustness” is a fully Bayesian approach which is not only sensitive to the local minimum like a standard $\chi^2$ comparison, but also to the entire likelihood and can in principle detect the presence of systematics in the dataset. The method works by analyzing combinations of subsets in the dataset in a Bayesian model comparison way, potentially finding groups of outliers, data affected by systematics or groups that might follow different physics.

The main goal of our approach was to identify systematic-contaminated data-points, which can then be further analyzed and potentially excluded if they cannot be corrected. Furthermore, in order to validate our analysis and assess its sensitivity we also performed several cross-checks, for example by removing some of the data points or by artificially contaminating some points, while we also generated mock datasets in order to estimate confidence regions of the iR.

We found that, in the first case, when removing the two points with the least robustness the iR for SSS>6 has a higher minimum but the maximum iR is lower, as well as the mean iR values are smaller with respect to the full dataset. In the second case, by adding an artificially contaminated point which was $\sim 5\sigma$ away from its actual value, we found that the internal robustness method indeed detected the inconsistency caused by the contaminated datapoint.

In conclusion, implementing the iR methodology we found that the $f_{\sigma_8}(z)$ dataset, used in our analysis and shown in Table I, is internally robust showing no anomalous behavior, thus ensuring its internal robustness. This is interesting when discussing the tension of the Planck 15 CMB data and the low redshift measurements coming from galaxy surveys, as we can make sure that the discrepancy does not originate from inconsistencies in the data.
