Abstract

Many recent successful off-policy multi-agent reinforcement learning (MARL) algorithms for cooperative partially observable environments focus on finding factorized value functions, leading to convoluted network structures. Building on the structure of independent Q-learners, our LAN algorithm takes a radically different approach, leveraging a dueling architecture to learn decentralized best-response policies via individual advantage functions. The learning is stabilized by a centralized critic whose primary objective is to reduce the moving target problem of the individual advantages. The critic, whose network’s size is independent of the number of agents, is cast aside after learning. Evaluation on the StarCraft II multi-agent challenge benchmark shows that LAN reaches state-of-the-art performance and is more scalable with respect to the number of agents, opening up a new promising direction for MARL research.

Keywords: Reinforcement Learning, Multi-Agent, Centralized Training with Decentralized Execution

1. Introduction

Reinforcement learning (RL) (Sutton and Barto, 1998) is the branch of machine learning dedicated to learning through trial-and-evaluation by interaction between an agent and an environment. Research in RL has successfully managed to exceed human performance in many tasks including Atari games (Mnih et al., 2015) and the challenging game of Go (Silver et al., 2016).

While single-agent RL has been highly successful, many real world tasks – sensor networks (Mihaylov et al., 2010), wildlife protection (Xu et al., 2020), and space debris cleaning (Klima et al., 2018) – require multiple agents. When these agents need to act on local observations, or the problem becomes too large to centralize due to the exponential growth of the joint action space in the number of agents, an explicitly multi-agent approach is required. As such, Multi-Agent Reinforcement Learning (MARL) (Busoniu et al., 2008; Hernandez-Leal et al., 2019; Shoham et al., 2007) introduces additional layers of complexity over single-agent RL.

In this paper, we focus on partially observable cooperative MARL where the agents optimize the same team reward. This setting introduces two main challenges that do not exist in single-agent RL. 1) The moving target problem (Tuyls and Weiss, 2012): the presence of multiple learners in an environment makes it impossible for an agent to infer the conditional probability of future states. This invalidates most single-agent approaches, as the Markovian property no longer holds. 2) The multi-agent credit assignment problem: to learn a policy each agent needs to determine which actions contribute to obtaining the maximum reward. While in single agent RL this problem is only temporal, as the reward can be sparse and delayed, the shared reward increases the complexity of this problem as the agents also need to determine their individual contribution.

Centralized Training with Decentralized Execution (CTDE) \citep{oliehoek2008a,foerster2018,lowe2017}, has become a popular learning paradigm for MARL. The core idea behind CTDE is that even though decentralized execution is required the learning is allowed to be centralized. Specifically, during training, it is often possible to access the global state of the environment, the observations and actions of all agents allowing to break partial observability, which mitigates both the moving target problem and the credit assignment problem.

Most of the research in off-policy CTDE MARL for collaborative partially observable environments focuses on factorizing the joint Q-Value into local agent utilities such as QMIX \citep{rashid2018} and QPLEX \citep{wang2021}.

In this paper, we take a radically different approach. Our Local Advantage Networks (LAN) algorithm learns for every agent the advantage of the best response policy to the other agents’ polices. These local advantages, which are solely conditioned on the agent observation-action history, are sufficient to build a decentralized policy. In this sense, the architecture of LAN resembles independent Q-learners more than other CTDE approaches such as QMIX or QPLEX. A key element of our solution is to derive a proxy of the local Q-value that leverages CTDE to stabilize the learning of the local advantages. For each agent the Q-value proxy is composed of the sum of the local advantage with the centralized value of the joint policy. Compared to the local Q-value, LAN’s proxy is able to provide better updates by breaking the partial observability and mitigate the moving target problem by integrating the changes of the other agents’ policies faster. As LAN learns the local advantage function for each agent it naturally reduces the multi-agent credit assignment problem as well. LAN is also highly scalable as the centralized value network reuses the hidden states of the local advantages to represent the joint observation-action history and the number of parameters of the centralized value does not depend on the number of agents. Finally, compared to QMIX, LAN does not factorize a joint function into individual components but rather reuses a centralized network to learn the agents’ advantages. This allows LAN to not have any restriction on the family of decentralized functions that it can represent as in cooperative environments the optimal policies are best response policies.

We empirically evaluate LAN against independent Q-Learners \citep{tan1993,tampuu2015} and state-of-the-art algorithms for deep MARL, i.e., VDN \citep{sunehag2018}, QMIX and QPLEX, on the Starcraft Multi-agent Challenge (SMAC) benchmark \citep{samvelyan2019}. We show that LAN achieves SOTA performance on all the maps. In the maps with the most agents, LAN’s centralized network uses up to 7 times fewer parameters than QPLEX demonstrating the scalability of our algorithm. Furthermore, in two super hard maps, LAN learns a complex strategy based on the agent sacrificing itself to lure the enemies far from its teammates, showcasing LAN’s capacity to mitigate the temporally extended multi-agent credit assignment problem. This strategy allows LAN to obtain a success rate of respectively 40% and 90% on two maps where the current state-of-the-art – QPLEX – struggles to obtain any wins. LAN’s average final performance on the 14 maps scores 10% more than QPLEX. We thus conclude that our approach of coordinating the learning of the local advantage functions with the centralized value-function conditioned on the agent’s hidden states performs well and is highly promising, as it not only performs better, but also scales better in the number of agents in terms of the number of parameters required. LAN opens up a promising alternative research area to value factorization for learning in Dec-POMDPs.

2. Background

The setting considered in this paper are Dec-POMDPs \citep{oliehoek2016,oliehoek2008a} \( G = \langle A, S, U, P, R, O, \tau, \gamma \rangle \). At each time-step, every agent \( a \in A \) selects an action \( u_a \in U_a \) to form the joint action \( u \in U \), where \( U = \prod_a U_a \), that is processed by the environment to produce: a unique reward \( r \) common to all agents; the next state \( s' \in S \); and the agents’ joint observation \( o \in O \), where \( O = \prod_a O_a \), with \( o_a \in O_a \) the observation of agent \( a \). As the agents cannot access the real state of the environment they condition their policy on their observation-action history \( \tau_a \in T_a \equiv (O_a, U_a)^* \), with \( \tau \in T \), where \( T = \prod_a T_a \) being the joint observation-action history. We refer to the observation-action history of an agents as its history, and the joint observation-action history as the joint history. To simplify the notations in this paper we assume that the observation function is deterministic. However the extension to stochastic observations is straightforward. With that setting, the next joint history \( \tau' \) is defined entirely by the current joint history, the joint action and the state \( (\tau, u, s') \). The value, Q-value and advantage functions of the joint policy \( \pi \), which can be centralized or decentralized, are defined as:
Local Advantage Networks

\[ V^\pi(s, \tau) = \sum_u \pi(u|\tau) [R(s, u) + \gamma \sum_{s'} P(s'|s, u)V^\pi(s', \tau')] \]
\[ Q^\pi(s, \tau, u) = R(s, u) + \gamma \sum_{s'} P(s'|s, u)V^\pi(s', \tau') \]
\[ A^\pi(s, u) = Q^\pi(s, u) - V^\pi(s) \]

We note that, if there is only a single agent a Dec-POMDP is a POMDP, and if this agent can observe the full state the POMDP is an MDP.

DQN (Mnih et al., 2013) is a popular algorithm for MDPs that learns an approximation of \( Q^* = \max_\pi Q^\pi \) with a neural network parametrized by \( \theta \). This \( \theta \) is learned through gradient descent by minimizing \( (Q(s, u | \theta) - y)^2 \) with \( y^{DQN} = r + \gamma \max_{u'} Q(s', u' | \theta) \). DQN uses a replay buffer to improve sample efficiency and to stabilize the learning. Dueling DQN (Wang et al., 2016) is a variant of DQN that learns both the value and the advantage, to then produce the Q-value as the sum of both instead of learning directly Q. This alternative architecture is motivated by the fact that one part of the neural network that learns the general value of the state, and a second part that learns the effects of the actions - represented by the advantage - can be easier than learning both in the same network. DRQN uses a Recurrent Neural Network (RNN), such as a Gated Recurrent Network (GRU) (Cho et al., 2014) or an LSTM (Hochreiter and Schmidhuber, 1997), to extends DQN to partial observability (POMDP). DQN can also be used to train independent Q-learners (Tampuu et al., 2015) for Dec-POMDPs.

3. Method

In this section, we present Local Advantage Networks (LAN) a novel value-based algorithm for collaborative partially observable MARL. LAN goes in the opposite direction of the current state-of-the-art in MARL, which focuses on factorizing the Q-value of the joint policy \( Q^\pi \) into individual utilities. Instead, LAN learns for each agent the best response policy to the other agents’ policies. The local advantages are only conditioned on the own agent’s history allowing for decentralized execution. The main contribution of LAN is to stabilize the learning of those advantages by leveraging CTDE to use the value of the joint policy \( V^\pi \) to coordinate their learning. The centralized nature of \( V^\pi \) allows to reduce the partial observability, and mitigate the moving target problem and the multi-agent credit assignment problem. By combining the local advantages with the centralized value, LAN derives a proxy of the local Q-values to simultaneously learn all components with DQN. Two key differences with a factorized Q-function are: (1) that LAN does not learn the Q-value of the joint policy, which is in fact more difficult to learn than the value \( (V) \), and (2) that in contrast to VDN and QMIX, LAN can represent all decentralized policies. We note that QPLEX can also represent all these policies.

We start from the observation that in a Dec-POMDP when the agents reach an optimal policy, their individual policies are best responses to the other agents’ policies. Indeed, if one agent could improve its policy while the other agents polices are fixed, the joint policy cannot be optimal as the agents share the same reward. Based on this observation, LAN focuses on learning best response polices.

To better understand how to learn best response policies, we first focus on a single agent \( a \in A \) and assume that the joint policy of the other agents \( \pi_{-a} \) is fixed. As in (Foerster et al., 2017), we derive from the Dec-POMDP \( G_a = \langle \tilde{S}, U_a, P_a, O_a, O_a, R_a, \gamma \rangle \), with \( \tilde{S} = \langle S, \mathcal{T}_{-a} \rangle \) being the original state space extended with the observation-action histories of the other agents, \( P_a \) and \( R_a \) are defined as follows:

\[ P_a(\tilde{s}'|\tilde{s}, u_a) = \sum_{u_{-a}} \pi_{-a}(u_{-a}|\mathcal{T}_{-a}) P(s'|s, (u_a, u_{-a})) \]
\[ R_a(\tilde{s}, u_a) = \sum_{u_{-a}} \pi_{-a}(u_{-a}|\mathcal{T}_{-a}) R(s, (u_a, u_{-a})) \]

The value, Q-value and advantage of \( G_a \) can then be derived as follows, with \( P(\tilde{s}|\mathcal{T}_a) \) the probability of being in an extended state \( \tilde{s} \in \tilde{S} \) when \( \mathcal{T}_a \) is agent \( a \)'s local history.
Due to the partial observability, agent \( a \) needs to disambiguate the state of \( G_a \) corresponding to the state of the Dec-POMDP \( G \) and the joint history of the other agents. As the environment is no longer Markovian, the agent needs to base its policy on a belief over the extended state. The most straightforward way to compute this belief is to keep the full history of the agent. However, this strategy does not scale well in the number of time-steps or state space. As analyzed in the work on influence-based abstractions (Oliehoek et al., 2012), in a Dec-POMDP maintaining a belief over the subset of features that allows to locally regain the Markovian property is sufficient, using the property of d-separation. This belief is much more compact than keeping track of the entire action-observation history, and therefore offers the possibility to keep a fully sufficient representation that remains tractable. In the ideal case, the RNN’s history representation will capture the belief over the d-separating features, enabling the reinforcement learning agent to learn an optimal Dec-POMDP policy. In practice of course, we aim to closely approximate such a representation, but are often uncertain of its existence, or of its size if it does exist.

Applying DQN to the single-agent POMDP \( G_a \) learns, for each agent \( a \), the best response policy to \( \pi_{-a} \), as the probability distribution over the relevant features \( P_a \) results from executing fixed policies for the other agents. A naive solution to learn good decentralized policies would therefore be to improve each agent successively. However, this approach fails if the environment requires the agents to explore simultaneously to find the optimal policy. On the other hand, optimizing \( Q^a \) for all the agents simultaneously, i.e., Independent Q-Learning (IQL) (Tan, 1993; Tamppu et al., 2015) also has key downsides. While IQL allows agents to explore together, it does not perform well in more complicated tasks due to the moving target problem as it ignores that the environment \( G_a \) perceived by agent \( a \) is shifting as \( \pi_{-a} \) evolves. So while we need agents that learn together, they need to do so in a coordinated manner.

LAN simultaneously learns best response policies and mitigates the moving target problem. These best response policies are expressed as local advantage functions that are solely conditioned on the agent’s observation-action history, \( A^a(\tau_a, \tau_a, u_a) \). To coordinate the learning of those local advantage functions, following the CTDE paradigm, LAN leverages full information about the states and the other agents observation-action history at training time via a centralized value function \( V^\pi \). More specifically, LAN derives \( \tilde{Q}^a_\pi \) a proxy of the local Q-value \( Q^a_\pi \) for each agent \( a \in A \).

\[
\tilde{Q}^a_\pi(s, \tau, u_a) = V^\pi(s, \tau) + A^a(\tau_a, \tau_a, u_a)
\] (1)

The proxy is constructed by summing the local advantage \( A^a_\pi \) with the centralized value of the joint policy \( V^\pi \). While \( \tilde{Q}^a_\pi \) is not a real Q-value and it is conditioned on the full state and the joint history \( \tau \) it can be used to extract decentralized policies as the maximizing actions only depend on the agent’s history \( \tau_a \), as shown by equation 2.

\[
\arg \max_{u_a} \tilde{Q}^a_\pi(s, \tau, u_a) = \arg \max_{u_a} A^a_\pi(\tau_a, u_a) = \arg \max_{u_a} Q^a_\pi(\tau_a, u_a)
\] (2)

LAN uses DQN to learn \( \tilde{Q}^a_\pi \) for all agents \( a \in A \) simultaneously. This allows LAN to learn the local advantages \( A^a_\pi \) and the centralized value \( V^\pi \) in parallel by optimizing a unique loss, resulting in an efficient learning scheme. LAN’s DQN target for agent \( a \) is defined as follows with the subscript \( t \) referring to a delayed copy of the networks to increase learning stability (van Hasselt et al., 2015).

\[
y_a = r + \gamma \tilde{Q}^a_\pi(s', \tau', \arg \max_{u_a} \tilde{Q}^a_\pi(s', \tau', u_a))
\]

\[
y_a = r + \gamma [V^\pi_\pi(s', \tau') + A^a_\pi(\tau'_a, \arg \max_{u'_a} A^a_\pi(\tau'_a, u'_a))]
\] (3)

(4)
Compared to the local Q-value $Q^\pi$, the learning of LAN’s proxy $\tilde{Q}_\pi^a$ has four interesting properties that help stabilize and coordinate the learning, and give an intuition on how LAN solves the task as a whole. We note that these properties result from applying DQN to LAN’s Q-value proxies to all agents in parallel, and cannot be tested independently.

First, $\tilde{Q}_\pi^a$ allows to provide better update targets by breaking the partial observability. In a POMDP, the same observation-action history can be linked to different states forcing the agent to learn a Q-value that marginalizes over the possible states. In a Dec-POMDP this problem becomes harder as all the agents $a \in A$ need to marginalize over the possible states but also over the possible joint histories of the other agents $\langle s, \tau-r \rangle$ as shown by the derivation of $G_a$. By its conditioning on the next state and the joint history $\langle s', \tau' \rangle$, LAN’s DQN target does not suffer from the partial observability and can therefore provide more accurate updates. As highlighted by (Lyu et al., 2021), using a centralized target to learn a decentralized object might lead to high variance updates. In LAN, this is partly mitigated by using a centralized value instead of a centralized Q-value. Indeed, $V^\pi$ helps providing better targets updates while not being as precise as $Q^\pi$, as the value is equal to the expectation of the Q-value with respect to the joint policy.

Second, $\tilde{Q}_\pi^a$ mitigates the moving target problem, which results from all the agents learning at the same time. This simultaneous learning allows the agent to explore together, which is necessary to find an optimal strategy in non-monotonic environments, but because of it the environment is constantly changing and locally loses its Markovian property. To provide meaningful updates and prevent the learning to plateau prematurely as in IQL, the updates need to reflect as closely as possible the ever changing environment. LAN achieves this thanks to the centralized value, which coordinates the learning of all the local advantages. This happens in two steps. First, as an update of $\tilde{Q}_\pi^a$ results in the update of both the centralized value and the local advantage with the same transitions, a modification of a local advantage function results in a change of the centralized value. Second, as the centralized value is part of the target update of every agent’s Q-value (eq. 4), the change is then propagated to the other agents’ advantage.

Third, $\tilde{Q}_\pi^a$ mitigates the multi-agent credit assignment problem. As the centralized value function approximates the expected return of the joint policy, the agents can easily evaluate the effect of their actions on the effective return simply by subtracting it the centralized value. This difference is then learned by the local advantages. Indeed, by applying DQN to $\tilde{Q}_\pi^a$, the local advantage network of agent $a$ (eq. 5) is updated with the following target which is similar to the one used by COMA (Foerster et al., 2018) to reduce the multi-agent credit assignment problem.

$$y_{A_a} = r + \gamma \tilde{Q}_{t_a}^\pi(s', \tau', \arg\max_{u_a} \tilde{Q}_a^\pi(s', \tau', u_a')) - V^\pi(s, \tau)$$ (5)

Fourth, $\tilde{Q}_\pi^a$ reduces the learning complexity of the decentralized policy. Extracting a policy from a value based algorithm is usually done by taking the maximizing action of the Q-value, or of the advantage as it has the same action ordering. As the advantage contains less information it is usually easier to learn (Wang et al., 2016). However, the advantage cannot be learned on its own and it requires to learn the corresponding value, which suffers from both the partial observability and the moving target problem. Therefore, LAN’s proxy offers a simple and efficient way to learn the local advantages without the local value.

To overcome the partial observability the local advantages networks use a GRU which learns to represent the observation-actions history into a hidden state $h_a$, with the aim to capture the necessary features to locally regain the Markov
property as stated above. This hidden state is then used to compute the local advantages. LAN leverages the work done at the agent level to represent \( \tau \) to build a representation of \( \tau \).

For each agent \( a \) the centralized value network combines the id \( a \) of the agent with its hidden state \( h_a \), its last observation \( o_a \) and its last action \( u_a \) into a vector \( \tilde{h}_a = [h_a, o_a, u_a, a] \). An embedding \( \hat{h}_a \) of \( h_a \) is then computed using the same feed-forward network for all agents if all the agents have similar types of observations and actions, or with a different feed-forward network per type. Finally, the centralized value network uses the sum of those embeddings \( \hat{h} = \sum_a \hat{h}_a \) to represent \( \tau \). LAN’s architecture, represented in Figure 1, provides two main benefits. First, the centralized value network does not learn a second recurrent network, which are knowingly difficult to train. Second, as the embedding for all agents are computed with the same weights, the number of parameters of the centralized value network does not depend on the number of agents.

4. Experiments

To benchmark LAN we use the StarCraft Multi-Agent Challenge\(^1\) (SMAC) (Samvelyan et al., 2019), a set of environments that runs in the popular video game StarCraft II. SMAC does not focus on the full game but rather on micromanagement tasks where two teams of agents - possibly heterogeneous and imbalanced - fight. A match is considered won if the other team is eliminated within the time limit. The time limits differ per task. Each agent only observes its surroundings and receives a team reward proportional to the damage done to the other team plus bonuses for killing an enemy and winning. The action space of each agent consists of a move action to each cardinal direction, a no-op action, and an attack action for each enemy which is replaced by a heal action for each team member for the Medivacs units. The attack/heal action only affects units within range. As the agent’s observation and action space are linearly dependent on the number of agents to perform well scalability is a key issue. SMAC also provides the real state of the environment, which we use as input for the centralized value. The benchmark is composed of 14 different maps that are designed to assess different aspects of cooperation. They are ranked into 3 categories: easy, hard, and super hard maps.

4.1 Configuration

To ensure a fair comparison, the decentralized network architecture, the version of the game, the \( \varepsilon \)-annealing parameters, the batch size, the replay buffer size, the use of a single environment, and the use of a unique set of parameters across all maps is consistent with the QMIX and QPLEX papers. Appendix B lists the hyper-parameters used, and Appendix D includes a discussion on why we do not force the advantage to have a zero-mean as in Dueling DQN (Wang et al., 2016). The training and evaluation follows the procedure described in Samvelyan et al. (2019), namely 2 million training timesteps, and evaluation of the decentralized greedy policies over 32 episodes every 10k timesteps. We train LAN on at least 5 different random seeds and report the median of the battle win rate over the learning time as well as the first and third quantiles.

4.2 Results

We compare LAN to IQL, VDN, QMIX and QPLEX. For QPLEX we use the implementation of the authors and for the other algorithms we use the run data made available by SMAC. In the following, we present LAN’s performance on 8 maps (Figure 2) with the maps in the first row featuring an increasing number of agents, and the maps in the second row being 4 super-hard maps. Finally, we discuss LAN’s average performance across all maps (Figure 3).

In the first three maps of Figure 2, two unbalanced teams with homogeneous units fight against each other, with our team composed of fewer units than the enemy: in 5m_vs_6m 5 agents fight 6 enemies, in 10m_vs_11m 10 agents fight 11 enemies, and in 27m_vs_30m 27 agents fight 30 enemies. The ratio between the number of agents and the number of enemies makes the map 10m_vs_11m easier compared to the other two. In the map 27m_vs_30m, both the number of agents and the dimension of the observation and action space constitute a real challenge for MARL. In those three maps, LAN dominates IQL and performs on par with SOTA. First, as IQL is a natural ablation of LAN,

---

1. We use version SC2.4.6.2.69232 and not SC2.4.10. Performances are not comparable between versions.
we deduce from this experiment that the centralized value introduced by LAN does indeed help to coordinate the learning of the agents and that LAN can address the shortcomings of IQL. Second, while LAN performs on par with the SOTA, it is more scalable than QMIX and QPLEX in terms of parameters of its centralized component with respect to the number of agents (Table 1). Indeed, between 5m\text{ vs }6m and 27m\text{ vs }30m the number of agents is multiplied by 5.4 and the number of parameters of LAN’s centralized value is only multiplied by a factor of 2, while for the centralized component of QMIX and QPLEX this factor is respectively 8.8 and 16.5. The last map of the first row of Figure 2, bane\text{ vs }bane, opposes two large and balanced teams of 24 heterogeneous units. We observe that while IQL easily reaches 100\% of wining rate, VDN struggles to learn and QMIX fails to learn. This hints at a limitation of both monotonous mixing strategies regarding scaling to a large number of agents, supporting our claim that an alternative research direction to value factorization is needed. QPLEX is able to learn the perfect strategy at the cost of doubling the number of parameters compared to QMIX. LAN also learns to consequently eliminate the opposing team and reaches a perfect score with 5 times fewer parameters than QPLEX. We highlight that the dependency of the dimension of the observation and action space in the number of agents is the only cause of the difference in the number of parameters of LAN’s centralized value network in the different maps.

The second row of Figure 2 presents LAN’s performance on 4 super-hard maps. The first super-hard map, 2c\text{ vs }64zg, matches two powerful agents against 64 weaker agents. The numerous enemies make the action space very large, with 70 actions, which is a known challenge in RL (Zahavy et al., 2018). In this map, LAN and QPLEX reach the same final performance with an 80\% win rate, while QMIX and VDN score respectively around 50\% and 20\%. IQL struggles to learn and does not exceed a 5\% win rate. The second super hard map, MMM2, features two unbalanced heterogeneous
teams, with the enemy team having 2 additional units, and is the only map including medical units. While IQL and VDN do not obtain any wins, QMIX and QPLEX score 60% and 80% respectively. LAN obtains the same final performance as QPLEX. In the third super hard map, corridor, 6 agents of type ‘zealot’ fight a team 24 enemies of type ‘zerlings’. While the SMAC paper claimed that the only solution for this map was to take advantage of the terrain (a spawning zone connected to a second zone by a corridor) to limit the number of enemies that can attack our agents, LAN discovered another solution. One agent lures part of the enemies to a remote location while the rest fights the remaining enemies. After killing the bait a fraction of the enemies attack our agents while the majority go through the corridor to reach the second zone. Our agents defeat their attackers, and after regenerating part of their shields move to the second zone to finish off the enemies. While the current SOTA flattens to zero, LAN obtains an almost perfect score with around 90% success rate. On the last super hard map, \(3s5z\_vs\_3s6z\) (Figure 2 right), LAN learns good decentralized policies with a performance at around 40%. The only other algorithm that was able to achieve any wins is QPLEX with less than 10%. The strategy is similar as the one learned in corridor, a stalker (long-range unit) baits most of the enemy’s zealots (close combat units) into targeting him. It then flees far away from his teammates and sacrifices himself so that the other agents can kill the stalkers and remaining zealots. The agents can then easily kill the remaining enemies as they are no longer protected by any long-range support.

The reason for LAN’s performance in last two super-hard maps is its ability to train an agent to lure the enemies and to sacrifice itself for the survival of its team. We believe that this behavior is easier to discover with LAN than with the mixing algorithms because of the shared Value network, as it allows dead agents to benefit directly from the rewards scored by the other agents after their death. LAN, by focusing on learning best response policies instead of factorizing a joint Q-value, learns for each agent the policy that maximizes the team return. In the case of QMIX and QPLEX, the factorization introduces a form of individual rewards that the agents learn to maximize. If the individual rewards induced by the factorization are not aligned with the team reward, as in the baiting strategy, then the mixing strategies struggle to learn. The complex strategy learned by LAN demonstrates the capacity of LAN to mitigate effectively the multi-agent credit assignment problem.

As in the SMAC benchmark and QPLEX papers, Figure 3 shows, on the left plot, LAN’s general average performance on the 14 maps that compose the SMAC benchmark, and, on the right plot, the number of maps where each algorithm outperforms the others by a margin of at least \(\frac{1}{32}\). IQL only achieves 30% averaged median test wins and is the best on 0 maps. This under-performance was expected as it is the only fully decentralized learning algorithm, and because it is highly vulnerable to the moving target problem. At the beginning of the learning, VDN and QMIX show similar performance, but, after \(1.25e^6\) timesteps, QMIX takes the lead obtaining 60% and beating VDN by 8%. QPLEX learns faster than the other algorithms and reaches the same final performance of QMIX in just a million timesteps to obtain 67% at the end of the learning. Finally, LAN learns faster than the baselines except QPLEX, which it exceeds at around \(1.25e^6\) timesteps. LAN finishes first with 77% wins. The right plot shows that LAN bests the other algorithms on 3 maps, namely corridor, \(3s5z\_vs\_3s6z\), 5m_vs_6m.
In summary, LAN performs on par with the SOTA on the easy and hard maps while dominating the other methods on the super hard maps, even the ones where the other methods did not achieve any wins. LAN outperforms QPLEX by 10% in averaged performance. These results showcase LAN’s performance and scalability potential, and its capacity to handle many agents and large observation and action spaces.

5. Related work

Applying single agent RL algorithms to Dec-POMDPs, such as Independent Q-Learners and Independent Actor-Critic, results in poor performance due to the moving target and credit assignment problems (Tan, 1993; Tampuu et al., 2015; Foerster et al., 2018) – with the exception of stateless normal form games (Nowe et al., 2012). The replay buffer, fundamental to DQN, worsens the moving target problem as the sampled transitions are quickly outdated and off-environment as the policies evolve. As removing the replay buffer does not lead to good policies, alternatives such as importance sampling and the use of fingerprints have been explored leading to small improvements (Foerster et al., 2017). LAN’s centralized value function however, mitigates the moving target problem sufficiently, which enables it to take advantage of the replay buffer and to reach state-of-the-art performance.

COMA (Foerster et al., 2018) and MADDPG (Lowe et al., 2017) introduced CTDE to Deep MARL by building on single-agent actor-critic algorithms but replacing the local critic with a centralized one. In comparison, our method, LAN, is a value-based algorithm making it more sample-efficient. While LAN’s joint value is also a centralized critic, it plays an intrinsically different role, as it fosters learning coordination between the local advantage functions.

In value-based methods for MARL, learning an approximate factorization of the joint Q-value into local utilities has been explored (Bargiacchi et al., 2021). In deep MARL, to ensure proper decentralized execution the factorization must follow the individual-global max (IGM) principle: the maximizing joint action of the joint Q-value must be equal to the joint action that results from maximizing the local utilities. To ensure IGM, the factorization usually enforces a monotonicity constraint, i.e., for each agent the derivative of the joint Q-value with respect to the agent’s local utility is positive. VDN is the first algorithm of this kind and decomposes the joint Q-value into a simple sum. QMIX extends VDN by learning state-dependent positive weights. The state dependency broadens the family of Q-value functions that can be learned. The positive weights constraint ensures IGM. QMIX achieves good performance and improves over VDN. However, it is still limited by the monotonicity constraint. QATTEN (Yang et al., 2020) extends QMIX by using a multi-head attention (Vaswani et al., 2017) to compute the mixing weights. More recently, QPLEX extends QATTEN by transferring the IGM principle from the Q-value to the advantage function. At the cost of twice as many parameters in average and a more complex mixing network, QPLEX outperforms QMIX on SMAC. In comparison, while our approach LAN does learn local advantage functions, it does not learn to factorize the joint advantage, leading to better results, and better scalability with regards to the number of parameters than QPLEX.

On a different direction, several algorithms focus on relaxing the monotonicity constraint. QTRAN (Son et al., 2019) transforms the problem into an optimization problem with soft constraints. While it achieves good performance in matrix games, it fails in more complicated environments due to the loss of IGM. QTRAN uses a similar technique as LAN to represent the joint history for its centralized Q-value, however as its embeddings are not conditioned on the agent ID it uses the same mapping for different types of agents. Also, as QTRAN learns a joint Q-value its neural network has at least a linear dependency in the number of agents for the number of parameters. WQMIX (Rashid et al., 2020) extends QMIX by focusing on representing the value of good joint actions more accurately, at the expense of the accuracy for suboptimal actions. While in some maps of StarCraft WQMIX improves over QMIX, its overall performance is similar (Wang et al., 2021).

Improving multi-agent exploration or scalability regarding the action space in DecPOMDPs have been successfully explored by MAVEN (Mahajan et al., 2019) and RODE (Wang and Dong, 2020). Both works are orthogonal to ours, and while they use QMIX as a base algorithm they could also be applied to LAN. For this reason we do not include them as baselines.

Recently, MAPPO (Yu et al., 2021) and IPPO de Witt et al. (2020) proved that actor-critic-based algorithms could achieve good performance on cooperative MARL. However, they require significantly more interactions, 10 million timesteps instead of 2 million, and more computing power. Comparison with those two algorithms is also harder because MAPPO changed the state space, IPPO changed the difficulty of the enemy team, and they do not use the same version of the environment. Also, they both have different hyperparameters per map whereas the other algorithms have one set of hyperparameters for the full benchmark challenge.
6. Conclusion

In this paper, we proposed Local Advantage Networks (LAN); a novel value-based MARL algorithm for Dec-POMDPs. LAN leverages the CTDE approach by building, for each agent, a proxy of the local Q-value composed of the local advantage and the joint value. LAN trains both networks by applying DQN to a Q-value proxy. The centralized learning allows to condition the joint value on the real state to overcome the partial observability during training. In parallel, it learns the advantages together with the joint value, to synchronize all value functions to the ever changing policies. This results in more accurate DQN targets and mitigates the moving target problem. Conditioning the local advantages solely on the agent’s observation-action history, ensures decentralized execution. To ensure scalability, LAN’s joint value efficiently summarizes the hidden states produced by the GRUs of the local advantages to represent the joint history. Therefore, the number of parameters of this value function is independent of the number of agents.

We evaluated LAN on the challenging SMAC benchmark where we performed significantly better or on par compared to state-of-the-art methods, while its architecture is significantly more scalable in the number of agents. In the two most complex maps, LAN was able to learn a complex strategy where one agent would sacrifice itself for the survival of the team, and therefore proving experimentally LAN’s ability to mitigate the multi-agent credit assignment problem. We believe that the lean architecture of LAN for learning decentralized policies in a Dec-POMDP, inspired by influence-based abstraction, is key to learning efficiently in decentralized partially observable settings.

Most of the recent work in value-based Deep MARL for Dec-POMDP focused on improving the value factorization of QMIX. The need for a different research direction is therefore real, and LAN, by moving away from value factorization, embodies this alternative. LAN is not only able to achieve better performance than value factorization but is also more scalable parameter-wise.

7. Future work

In future work, we aim to explore how the history representation of the centralized value can be improved through the use of Attention (Vaswani et al., 2017) or Graph Neural Networks (Kipf and Welling, 2017). We also aim to investigate how explicit communication (Oliehoek et al., 2008b; Messias et al., 2011; Wang et al., 2020; Das et al., 2019) can be added to LAN to further improve the coordination between the agents and to improve robustness of the learned policies. We also plan to investigate how LAN’s architecture might benefit MARL algorithms in settings with continuous action spaces.

Appendix A. StarCraft Multi-Agent Challenge

The complete information about the SMAC benchmark can be found in the introductory paper (Samvelyan et al., 2019). Table 2 lists the 14 different maps of the challenge with the number of agents in each team and the number of parameters of the centralized part of LAN, QPLEX and QMIX. Table 3 lists the number of parameters of the centralized component of LAN, QMIX and QPLEX for the 14 maps.

Table 2: The different maps of SMAC.

| Map Name      | Ally Units                    | Enemy Units                    |
|---------------|-------------------------------|-------------------------------|
| 2s3z          | 2 Stalkers & 3 Zealots        | 2 Stalkers & 3 Zealots        |

Appendix B. Implementation details

We use neural networks with ReLu activation functions, to approximate the local advantage and the centralized value. To increase the learning speed and reduce the number of parameters we share the neural network weights of the local advantages between all the agents. The input of the advantage network conditions on the agent ID so that the policy can differ per agent. The advantage network is composed of a 2 hidden layers, a 64 units feed forward network and a 64 units GRU, which is consistent with the architecture used in the SOTA algorithms to represent the decentralized utilities (Rashid et al., 2018; Wang et al., 2021).
LOCAL ADVANTAGE NETWORKS

The centralized value network (Figure 1, left) first computes an embedding of $\tilde{h}_a$ for each agent, $\hat{h}_a$, using a feed forward network of 128 units. The agents’ embeddings are then merged together by summing them resulting in a joint history embedding of fixed size. This joint history embedding is then concatenated with the real state provided by the environment to create a state-history embedding. Finally, this state-history embedding goes through an feed forward network of two hidden layers of 128 units to compute the value.

We train LAN for 2 million timesteps using a replay buffer of 5k episodes. During training we use an $\varepsilon$-greedy exploration strategy over the local advantages, with $\varepsilon$ decaying from 1 to 0.05 over the first 50k timesteps. After every episode we optimize both networks twice using Adam with a learning rate of $5e^{-4}$ and without TD($\lambda$). For each update we sample a batch of 32 episodes from the replay buffer. The DQN target are computed with a target network that is updated every 200 gradient updates. We clip to 10 the norm of the gradient.

We note that LAN does not require parameter sharing, and that each type of agent could have its own model. In that case, every agent type also needs its own embedding network to compute $\tilde{h}_a$.

Appendix C. Remaining maps of SMAC

Figure 4 includes the 6 SMAC maps that are not included in the main paper. The first map, 2s_vs_1sc, is an easy map and LAN learns the perfect strategy as the other algorithms do. In the second and third maps, 2s3z and 1c3s5z, all the algorithms but IQL learn near-optimal policies. In 3s_vs_5z, LAN and QPLEX learn the optimal policy followed closely by QMIX and VDN that both reach around 85%. In 3s5z, LAN reaches the same performance as VDN with 80% median battle won rate whereas QMIX and QPLEX obtain 100%. This underperformance is intriguing as LAN performs better than the other algorithms in 3s5z_vs_3s6z, the harder version of the map. By visualizing the learned policies in 3s5z we discovered that LAN converges to two different policies: a) a basic confrontation policy which is the policy learned by QMIX and QPLEX; b) a baiting strategy identical to the one learned in 3s5z_vs_3s6z. We also remark that LAN appears to still be learning and might converge to 100% if given more time. Finally, in the last map 6h_vs_8z no algorithm is able to score any wins.
Appendix D. Discussion regarding the advantage

As the policies are deterministic, the local advantages should be negative with the maximizing value equal to 0. However as (Wang et al., 2016) studies, even when computing the real Q-value in single agent MDP enforcing this constraint has a negative impact on the learning. Their experiments showed that applying the following transformation to the output of the neural network provided better stability.

$$A^\pi_a(\tau_a, u_a) \leftarrow A^\pi_a(\tau_a, u_a) - \frac{1}{|U_a|} A^\pi_a(\tau_a, u_a)$$

In the single agent case, this result in the learned advantage to differ from the real advantage by a fixed offset. In LAN, as the centralized value is shared between all the agents, enforcing the local advantages to have a zero mean means that the offset will be shared between all the agents. As in (Wang et al., 2016), we investigated enforcing negative advantages and observed that the learning was also highly impacted by it in LAN. While sharing the offset between the agents can have a positive impact on collaboration it can also hinder the learning by adding an additional constraint on both networks - as showed by LAN’s performance with the mean constraint (eq. 6) in Figure 5. Therefore, in LAN we do not apply any constraint on the output of the advantage network.

Figure 5 shows the performance on all the SMAC maps with a variation of LAN called LAN mean, which applies the equation 6. While in two maps 3s5z, 27m_vs_30m the mean version of LAN improves over the classical version, it degrades the performance in others other maps such as 5m_vs_6m, 2c_vs_64zg, and MMM2, and prevents the learning in corridor and 3s5z_vs_3s6z. This empirically shows that while in the single agent case the equation 6 stabilizes the learning it might not be the case when multiple agents are involved.
Figure 5: Median battle won rate during learning on the all the SMAC maps.
