ARterial-CaRdiac INTERACTION: The Concept and Implications

CHI YOUNG SHIM, MD, PhD
CARDIOLOGY DIVISION, SEVERANCE CARDIOVASCULAR HOSPITAL, YONSEI UNIVERSITY COLLEGE OF MEDICINE, SEOUL, KOREA

Vascular stiffening of the large arteries is a common feature of human aging. Increased aortic stiffness with age may contribute to pathological changes in the left ventricle and this can induce ventricular stiffening. Vascular-ventricular stiffening combined with abnormal arterial-cardiac interaction is considered an important pathophysiology of heart failure with a preserved ejection fraction. Here, I briefly review the concept and implications of arterial-cardiac interaction and this will pave the way to understanding and controlling heart failure with a preserved ejection fraction, which is more prevalent in the elderly.

KEY WORDS: Aortic stiffness · Left ventricle · Heart failure.

INTRODUCTION

The circulatory system is a closed system. The heart and the vascular system interact to provide adequate blood flow throughout the body. This interaction of properties of the systolic ventricle, as a pump, and the vascular system, as a load, plays a critical role in determining cardiac output. Therefore, arterial-cardiac interaction, also known as ventricular-vascular interaction or ventricular-vascular coupling, is considered a central determinant of net cardiovascular performance. There has been much interest in the relationship among vascular stiffness, cardiac function, and cardiovascular diseases. The concept of arterial-cardiac interaction is important to understanding the pathophysiologies of heart failure, especially in patients with preserved ejection fraction. This review will focus on the concept and implications of arterial-cardiac interaction and the non-invasive methods available for its clinical assessment.

VASCULAR AGING AND STIFFENING

Vascular stiffening of the large arteries is a common feature of human aging and is exacerbated by many common disorders such as hypertension, diabetes mellitus, and renal disease. The normal aorta delivers blood from the heart to the capillaries and cushions pulsations. The arterial system in youth is a very effective conduit and a very efficient cushion. In young subjects, the wave travels slowly in the distensible vessels such as hypertension, diabetes mellitus, and renal disease. Such changes are more proclamable in the elderly. Elderly subjects have higher central BPs in similar peripheral BPs with younger subjects, that is, they have the same peripheral BPs, measured at the same central BPs. Central blood pressure (BP) is higher in elderly subjects. Elderly subjects have higher BS pressures (BP) differ even when they have the same peripheral BPs. Elderly subjects have higher central BPs in similar peripheral BPs with younger subjects, that is, they have the same peripheral BPs, measured at the same central BPs. Central blood pressure (BP) is higher in elderly subjects. In the age-related changes in central AIx and aortic PWV follow different patterns. Recently, PP amplification has been suggested as a mechanical biomarker of cardiovascular disease and risk, together with global arterial properties. Normally, differences in vessel stiffness and reflection of pressure waves within the arterial tree result in considerable amplification of PP between the aorta and brachial artery. This so-called PP amplification is a well-established hemodynamic phenomenon and reduced PP amplification is related to increased cardiovascular risks and poor outcomes superior to the values of brachial or central arteries alone. Ultrasound-based measurements of arterial stiffness are also in use. It is necessary to simultaneously measure BP. The stiffness index $\beta$ is less affected by arterial pressure changes and could be more useful than other parameters, being easily determined using ultrasound. Carotid stiffness index $\beta$ has been used to assess arterial stiffness in various cardiovascular diseases.

### Table 1. Indices and surrogates of arterial stiffness

| Methods                  | Parameter                    | Definition                                                                 |
|--------------------------|------------------------------|---------------------------------------------------------------------------|
| Pulse wave velocity      | Pulse wave velocity          | Velocity of the traveling pulse along a length of artery                  |
|                          | Time                         | Distance/AT (cm/s)                                                        |
| Pulse wave analysis      | Central pulse pressure       | The difference between the central systolic and central diastolic pressures |
| Augmentation index       | Central pulse pressure       | The difference between the second and first systolic peaks as a percentage of the pulse pressure |
| Pulse pressure amplification | Central pulse pressure     | Peripheral pulse/central pulse pressure                                   |
| Ultrasound               | Stiffness index $\beta$     | Ratio of the ln (systolic/diastolic pressure) to the relative change in the diameter $\beta = \ln(Ps/Pd)/(Ds- Dd/Dd)$ |

VENTRICULAR-VASCULAR COUPLING

THE CONCEPT AND ASSESSMENT OF VENTRICULAR-VASCULAR COUPLING

The interaction of ventricular and vascular properties, or coupling, is an important determinant of cardiac performance.1-3 Several groups of systems-physiology investigators have studied and clarified currently accepted frameworks of ventricular-vascular coupling.1-3,20-21 Many investigators have sought ways to characterize both the heart and vascular system and their interaction using common variables. Fig. 3 shows a schematic diagram of the pressure-volume loop for LV, with ventricular systolic and diastolic elastances, and effective arterial elastance.

**Noninvasive assessment of ventricular-vascular coupling**

Based on this concept, ventricular systolic elastance, effective arterial elastance, and the ventricular-vascular coupling index can be assessed noninvasively using echocardiography and simultaneously assessed BPs. LV end-systolic and end-diastolic volumes are measured from apical 4-chamber and 2-chamber views using the biplane method of disks (modified Simpson’s rule).22 Stroke volume can be calculated by subtracting the end-systolic volume from the end-diastolic volume. End-systolic pressure is approximated by \([2 \times \text{systolic BP} + \text{diastolic BP}] / 3\). This noninvasive assessment of end-systolic pressure accurately predicts LV pressure-volume loop measurements of end-systolic pressure.23 The Ea is estimated as the end-systolic pressure/stroke volume. The Ees of LV is calculated as end-systolic pressure/end-systolic volume. Ventricular-vascular coupling is generally assessed by the Ea/Ees ratio, termed the ventricular-vascular coupling index.3-4

**AGE-RELATED CHANGES IN VENTRICULAR-VASCULAR COUPLING**

Fig. 4A and B display typical pressure-volume data, along with Ees and Ea, for young and elderly subjects. In comparison with the younger subjects, the older subjects display marked increases in both elastances, reflecting vascular stiffening and ventricular stiffening.24 The result is that both parameters remain relatively matched. The matched increase in arterial and cardiac stiffness with aging can maintain ventricular-vascular coupling within a normal range.24-26 However, diastolic cham-

Dynamic changes of ventricular-vascular coupling

Although maintenance of ventricular-vascular coupling with age would be somewhat beneficial, the rise in both vascular and ventricular stiffening becomes apparently problematic when the system is stressed by exercise. In normal subjects, effective arterial elastance is nearly one half of LV elastance and the ventricular-vascular coupling index decreases with exercise, indicating augmented pump efficiency. Najjar et al. demonstrated that the ventricular-vascular coupling index during exercise decreased by a smaller degree in older subjects than in younger subjects even though there was no difference by age in resting ventricular-vascular coupling index (Fig. 5A). These findings might suggest that aging is associated with less reserve capacity, or an inability to attain maximal efficacy, manifested by a smaller reduction in the coupling index. The different responses of ventricular-vascular coupling to exercise can be related to exercise intolerance. In addition, higher ventricular and vascular stiffness has important implications regarding BP liability and loading sensitivity even though coupling is maintained with age. In the elderly, even a small increase in blood volume can substantially raise systolic BP (Fig. 5B). Therefore, enhanced BP sensitivity to circulating volume and diuretics is common in elderly subjects and the mechanism of rapid-onset pulmonary edema in elderly subjects can be explained. In summary, when the ventricular-vascular system is stressed with exercise or faced with volume overload, the coupling response may be abnormal, and it may be difficult to maintain effective cardiovascular performance.

In conclusion, abnormal arterial-cardiac interaction and stiffening of the ventricular and vascular systems may contribute to the pathophysiology of heart failure with preserved ejection fraction. Combined ventricular-vascular stiffening may have important consequences on cardiac response under stress by exertion, volume overload and abrupt changes in heart function. The major effects of ventricular-vascular stiffening can be summarized as follows: 1) enhanced liability of cardiovascular function; 2) limited reserve capacity; 3) greater pressure sensitivity to blood volume alterations; 4) greater likelihood of poorly matched ventricular-vascular system with cardiac failure; and 5) compromised coronary flow and exacerbated response to myocardial ischemia.
