ABSTRACT

Objective To determine whether restricting the use of inotrope after diagnosis of low blood pressure (BP) in the first 72 hours of life affects survival without significant brain injury at 36 weeks of postmenstrual age (PMA) in infants born before 28 weeks of gestation.

Design Double-blind, placebo-controlled randomised trial. Caregivers were masked to group assignment.

Setting 10 sites across Europe and Canada.

Participants Infants born before 28 weeks of gestation were eligible if they had an invasive mean BP less than their gestational age that persisted for ≥15 min in the first 72 hours of life and a cerebral ultrasound free of significant (≥ grade 3) intraventricular haemorrhage.

Intervention Participants were randomly assigned to saline bolus followed by either a dopamine infusion (standard management) or placebo (5% dextrose) infusion (restrictive management).

Primary outcome Survival to 36 weeks of PMA without severe brain injury.

Results The trial terminated early due to significant enrolment issues (7.7% of planned recruitment). 58 infants were enrolled between February 2015 and September 2017. The two groups were well matched for baseline variables. In the standard group, 18/29 (62%) achieved the primary outcome compared with 20/29 (69%) in the restrictive group (p=0.58). Additional treatments for low BP were used less frequently in the standard arm (11/29 (38%) vs 19/29 (66%), p=0.038).

Conclusion Though this study lacked power, we did not detect major differences in clinical outcomes between standard or restrictive approach to treatment. These results will inform future studies in this area.

Trial registration number NCT01482559, EudraCT 2010-023988-17.

INTRODUCTION

The definition and management of low blood pressure (BP) in preterm infants, particularly those born before 28 weeks of gestation, are controversial. Many preterm infants continue to receive intervention for low BP with little evidence to support such practices. In a recent multisite observational study, over 50% of extremely preterm infants received an intervention for low BP, and almost 30% received an inotrope. Surveys from Europe, Canada and Australia identified variations in the definition and treatment of low BP. The most frequently used indication for treatment was a mean BP below a predetermined threshold, typically defined as mean BP (measured in mm Hg) less than the infant’s gestational age or postmenstrual age in completed weeks.

Preterm infants are usually treated for low BP in the first 24 hours of life; the more immature they are, the more likely they are to be treated. The most commonly used treatment is a volume bolus followed by dopamine infusion. The overall incidence of low blood pressure is less than previously determined with less than one quarter of infants having at least one numerically low BP in the first days of life. The mean time to presentation with low BP is early, less than 6 hours.

Conducting studies of cardiovascular instability in extreme preterm infants is challenging, and alternative trial designs and consent strategies need to be considered.

What is already known on this topic?

► The most frequently used indication for treatment is a mean blood pressure (BP) below a predetermined threshold, typically defined as mean BP (measured in mm Hg) less than the infant’s gestational age in completed weeks.

What this study adds?

► The overall incidence of low blood pressure is less than previously determined with less than one quarter of infants having at least one numerically low BP in the first days of life. The mean time to presentation with low BP is early, less than 6 hours.

► Conducting studies of cardiovascular instability in extreme preterm infants is challenging, and alternative trial designs and consent strategies need to be considered.
short-term and long-term outcomes of inotrope therapy in hypotensive infants has yet been performed.\textsuperscript{14} The Hypotension In Preterm Infants (HIP) trial was designed to compare the standard management approach—saline bolus and dopamine infusion based on a GA threshold—to a more restrictive approach—saline bolus and placebo infusion, with further intervention dictated by assessment of the infant’s overall haemodynamic status within the first 72 hours after birth. We hypothesised that a more restrictive approach would improve survival without significant brain injury at 36 weeks of postmenstrual age (PMA) in infants born before 28 weeks of GA.

**METHODS**

**Study design**

The HIP trial was an international, multicentre, parallel design randomised trial that compared two strategies for the management of hypotension in infants born before 28 weeks of GA. Infants were enrolled at 10 sites across Europe and Canada between February 2015 and September 2017.

**Participants**

Infants were eligible for inclusion if they had all of the following: (1) a GA of <28 weeks at birth; (ii) an indwelling arterial line to monitor BP, suitably calibrated and zeroed with the measuring dome at the level of the infants mid-axillary line when supine; (3) a cranial ultrasound scan demonstrating no significant IVH (grade 3 or 4); and (4) low BP, defined as a mean BP of 1 mm Hg or more below a mean BP value equivalent to the GA in completed weeks, which persisted over at least a 15 min period within the first 72 hours of birth. Patients were ineligible if they were considered unlikely to survive by attending clinicians, had significant congenital anomalies or if there was evidence of frank hypovolaemia.

**Primary and secondary outcome measures**

The primary outcome was survival to 36 weeks of PMA free of severe brain injury on ultrasound. IVH was classified according to Volpe’s criteria and cystic periventricular leukomalacia according to de Vries criteria. We defined severe brain injury as IVH causing moderate or severe ventricular dilatation, intracerebral echodense lesions and cystic periventricular leucomalacia. Survival free of neurodisability at 2 years of corrected age was a coprimary outcome and will be reported at a later date. Prespecified secondary outcomes included all-cause mortality at...
36 weeks of PMA, IVH grade 3 or 4 at any age, periventricular leucomalacia and/or ventriculomegaly on cranial ultrasound at 36 weeks of PMA, total duration of intubation and need for additional BP support.

Consent and randomisation
Verbal and written information was provided to parents antenatally where possible. When antenatal consent was impractical, the parents were informed of the study as early as possible following delivery, and eligible infants were enrolled only when written consent was obtained. No deferred or waiver of consent was permitted. Group allocation was generated using a web-based system. Infants were randomly assigned in a 1:1 ratio in blocks of four. Randomisation was stratified by centre and GA (23–25 weeks and 26–27 weeks). Infants from multiple births were randomised independently. Local principal investigators performed the randomisation and provided the code to the pharmacist or nurse preparing the infusion.

Trial interventions
Infants were assigned to one of two groups (standard vs restrictive). Infants received an infusion of 10mL/kg of 0.9% saline administered over 20 min before commencing their allocated study drug contained in 50 mL syringes identical in appearance. In the standard group, the syringe contained dopamine in 5% dextrose, commenced at a rate of 5 mcg/kg/min. In the restrictive group, the syringe contained 5% dextrose. The dose of study drug was not increased if the mean BP rose to greater than the GA threshold. If the mean BP remained below the GA, the study drug was not increased in mcg/kg/min dopamine or equivalent. Infants received an infusion of 10mL/kg of 0.9% saline, unless otherwise stated. Group allocation was generated using a web-based system. Infants were randomly assigned in a 1:1 ratio in blocks of four. Randomisation was stratified by centre and GA (23–25 weeks and 26–27 weeks). Infants from multiple births were randomised independently. Local principal investigators performed the randomisation and provided the code to the pharmacist or nurse preparing the infusion.

Rescue therapy
Additional therapy (typically epinephrine) was indicated if criteria for poor perfusion were met. A combination of BP values, clinical signs (skin colour, urine output and heart rate)

and biochemical findings were considered. Additional therapy was indicated when the mean BP was more than 5 mm Hg below the threshold or when the infants had two or more of (1) mean BP of 3 mm Hg less than the threshold value, (2) lactate greater than 4 mmol/L and (3) prolonged capillary refill time (>4 s). Weaning of the study drug was as follows: if BP was 5 mm Hg greater than threshold, then study drug was reduced by 5 mcg/kg/min; if >10 mm Hg, it was reduced by 10 mcg/ kg/min; and if 15 mm Hg higher, the study drug was stopped. If an infant developed hypotension at a later stage during their stay, dopamine administration was prohibited. Alternative interventions included volume and alternative inotropes/vasopressors (epinephrine, dobutamine, norepinephrine and milrinone).

Sample size and analysis
This was calculated assuming that the proportion of infants under standard intervention experiencing the primary outcome would be 50% and the desired difference to detect an improvement to standard intervention experiencing the primary outcome would no more than 10%, we planned enrolment of 830 subjects.

RESULTS
There were 809 infants born before 28 weeks of GA at participating centres between February 2015 and September 2017. Overall, 197 infants (24%) had a low BP documented (invasively or non-invasively). Of the 809 patients, 307 had invasive BP monitoring. Thirty-six infants were ineligible due to an initial cranial ultrasound abnormality, while 9 were considered likely to die and 4 had congenital anomalies. Of the remaining 258 infants, 114 were hypotensive and met all inclusion criteria, and 58 (51%) consented. Reasons for non-inclusion are detailed in the Consolidated Standards of Reporting Trials diagram (figure 2). Baseline characteristics of enrolled infants are detailed in table 1 (maternal), table 2 (birth) and table 3 (enrolment) and show no major imbalances. The median age at enrolment was 5.28 hours (IQR 3.54–12.10 hours) in the standard care group and 6.12 hours (IQR 3.93–14.34 hours) in the restrictive management group. The mean BP at the time of enrolment was similar between the groups (21.4 mm Hg vs 21.5 mm Hg).

The primary outcome of survival free of ultrasound abnormality at 36 weeks was reached by 18/29 (62%) in the standard group and 20/29 (69%) in the restrictive group. The difference of 7% was not statistically significant (p = 0.58; OR 0.74; 95% CI 0.25 to 2.18).

| Table 4 | Primary outcome survival without severe ultrasound abnormality at 36 weeks of PMA |
|---------|--------------------------------|
|         | Standard (n=29) | Restrictive (n=29) | OR (95% CI)* | P value* |
| All Infants | 18 (62) | 20 (69) | 0.74 (0.25 to 2.18) | 0.58 |

Monitoring and regulatory issues
This study was part of a paediatric investigational plan (PIP) registered with the European Medicine Agency to develop a new paediatric dopamine formulation. The concentration of this ready-to-use product was 1.5 mg/mL of dopamine in a 30 mL vial. Drug production issues meant the final product was not available until the latter months of the project. However, drug preparation was standardised to reflect this concentration. Pharmacovigilance was conducted by the sponsor (BrePco Biopharma, Dublin). The Data Safety Monitoring Board comprised two independent neonatologists and a trial statistician. Clearly defined stopping rules were established based on safety and efficacy. After 2 years of enrolment, a decision was made by the trial steering committee to discontinue the study due to ongoing drug production issues, cessation of funding and the overall slow enrolment rate.

Table 5 | Secondary outcomes |

*Unless otherwise stated. †From logistic regression analysis unless otherwise stated. ‡Of those who had survived to 36 weeks. §Median (IQR). ¶n=21 in the standard group. **n=22 in the restricted group. ††Ratio of geometric means as the duration variable was log-transformed.

BPD, bronchopulmonary dysplasia; IVH, intraventricular haemorrhage; NEC, necrotising enterocolitis; PVL, periventricular leukomalacia; SIP, spontaneous intestinal perforation.
and by 20/29 (69%) in the restrictive management group (OR 0.74, 95% CI 0.25 to 2.18) (table 4). The frequency of the components of the primary outcome did not differ between groups. The frequency of the primary outcome or its components did not differ between groups in either GA stratum (ie, above or below 26 weeks of gestation). The frequency of each secondary outcome was similar by study group (table 5). Mean BP dynamics following commencement of investigational medicinal product are displayed in figure 3. Changes in mean BP from 0 to 2 hours differed between the placebo and dopamine groups (p=0.028 for group×time interaction). The largest difference between the two groups was at 30 min (difference in means 4.4, 95% CI 1.8 to 7.1, p=0.001).

Additional BP support was used less frequently in the standard group (11/29, 38%) compared with the restrictive group (19/29, 66%) (p=0.038). Fewer infants in the standard group received additional inotropes (28% vs 48%, p=0.11). Among infants <26 weeks of gestation, this difference was most marked (11% vs 63%, p=0.002). Of 22 patients who received additional inotrope, the majority, 19, received epinephrine; 5 receiveddobutamine; and 4 received hydrocortisone. Additional therapy was commenced based on mean BP, which was >5 mm Hg above the equivalent GA in seven cases, and in 12 cases, the mean BP was >3 mm Hg below but with additional clinical signs or abnormal lactate values. Two infants received open-label dopamine contrary to protocol during their neonatal intensive care unit stay beyond the first 72 hours.

DISCUSSION

In this placebo-controlled trial, the frequency of survival free of cranial ultrasound abnormality at 36 weeks of PMA was similar between both groups. However, our ability to draw robust conclusions is limited as the overall number of included patients was low, rendering the study significantly underpowered. Similar studies of cardiovascular support in newborns have concluded early.16-19 A randomised trial of hydrocortisone for neonatal hypotension terminated early16 because a large number of patients did not meet eligibility criteria and there were difficulties obtaining timely informed consent. Physician unwillingness to enrol, a complex factorial trial design and low parental consent rate were identified as key factors in another trial that randomised only 10 patients from an eligible population of 126.17 Timely consent and a declining incidence were major factors highlighted in a recent trial of pulmonary hypertension management.20 Clinicians may be unwilling to enrol extremely preterm infants with very low BP values, or may have decided to include other parameters, such as echocardiography, to decide on inclusion. Future trials will need to consider alternative approaches to diagnosis. Relatively short time lines to obtain consent may also be a major factor in parental refusal of consent. In our study, the mean time patients were enrolled was approximately 6 hours.

The study was reviewed by the Paediatric Committee of the European Medicines Agency21 as part of a PIP, which mandated an invasive arterial catheter and pre-enrolment ultrasound free of significant IVH. Deferred consent was not permitted. These relatively strict inclusion criteria likely impacted recruitment. Significant challenges were met in the development of a paediatric formulation, a finding similar to the Neocirc study, which published a pilot trial comparing dobutamine to placebo in low flow states.22

There has been a move towards less intervention in the setting of low BP.12 13 However, data from a recent matched cohort study suggests that treating isolated low BP is associated with less severe brain injury.23 Therefore, whether or not to treat isolated low BP remains to be answered. We hope that our findings will help inform future studies in this area. The overall prevalence of low BP was 25% but varied from 9% at one site to 32% at another. Previous Canadian Neonatal Network data suggested a prevalence of over 50%,24 and the German Neonatal Network reported a frequency of 52%.12 The Australian Placental Transfusion Study identified a rate of approximately 32%.25 Our data represent the most recent data in a prospectively recorded group of extremely preterm infants delivered at tertiary centres across four countries. The wide variability may reflect different practices including timing of cord clamping,25-27 modes of mechanical ventilation28 (premedication and sedation) and presence of an invasive arterial line.

The need to enrol infants to studies shortly after birth places significant pressure on families to consent and alternative recruitment strategies need to be sought. In studies of therapeutic hypothermia,29 consent could only be obtained postnatally following the recognition of an encephalopathic infant. However, in a trial such as this, it could be anticipated from knowledge of the GA. A stepped and continuous consent process might be preferable with formal deferred consent. Antenatal consent is feasible but requires significant resources, as similar to the Surfactant Positive Airway Pressure and Pulse Oximetry Trial,30 many parents would need to be approached to enrol one infant. Our data suggest approaching a minimum of eight families antenatally to enrol one infant.

We identified some important patient characteristics. A disproportionate number were male (70%) and the majority (85%) were intubated. Mean BP for the group overall was low (21.3 mm Hg) at the time of randomisation, with a normal lactate value. This suggests that while the BP reading was low, perfusion was satisfactory, reflective of the problem being addressed. The overall mortality for the entire cohort was 22%. The overall rate of cranial ultrasound abnormality was 50%, but with severe cranial ultrasound abnormality present in only 15%, to give a combined overall primary outcome of 34%. Of those recruited, 11 (19%) had either necrotising enterocolitis or spontaneous intestinal perforation. Consideration should be given to other clinically relevant endpoints in future studies of cardiovascular support, in particular, the inclusion of gastrointestinal complications. Long-term outcome is ongoing for the enrolled infants.
In conclusion, conducting trials of haemodynamic support in extremely preterm infants is challenging. We did not detect differences in clinical outcomes between standard or restrictive approaches to management and so cannot comment on which treatment approach is superior. These results will inform future studies in this area.
