The laurel family within the Magnoliids has attracted attentions owing to its scents, variable inflorescences, and controversial phylogenetic position. Here, we present a chromosome-level assembly of the **Litsea cubeba** genome, together with low-coverage genomic and transcriptomic data for many other Lauraceae. Phylogenomic analyses show phylogenetic discordance at the position of Magnoliids, suggesting incomplete lineage sorting during the divergence of monocots, eudicots, and Magnoliids. An ancient whole-genome duplication (WGD) event occurred just before the divergence of Laurales and Magnoliidae; subsequently, independent WGDs occurred almost simultaneously in the three Lauralean lineages. The phylogenetic relationships within Lauraceae correspond to the divergence of inflorescences, as evidenced by the phylogeny of **FUWA**, a conserved gene involved in determining panicle architecture in Lauraceae. Monoterpene synthases responsible for production of specific volatile compounds in Lauraceae are functionally verified. Our work sheds light on the evolution of the Lauraceae, the genetic basis for floral evolution and specific scents.

Lauraceae, also referred to as the laurel family, is a family from the order Laurales in Magnoliids. The family includes a total of 2500–3000 globally distributed species in 44 genera of the woody subfamily Lauridoideae and about 25 species in 1 genus of the parasitic subfamily Cassythidoideae. The morphological features of flowers in Lauraceae species, including various inflorescences and the existence of both bisexual and unisexual flowers, provide a reference for studying flower evolution in angiosperms. In addition, the specific scents from Lauraceae species have made the laurel family economically important as a source of medicine, spices, and perfumes. A diverse array of terpenoids, mainly monoterpenes and sesquiterpenes, defines the scents of different species in Lauraceae. Terpene synthases (TPSs) have been primarily responsible for the monoterpene production; however, research on the TPS gene families in Lauraceae is still in its infancy due to the hitherto limited genomic data. From a phylogenetic perspective, the relationships among Magnoliids, monocots, and eudicots still remain to be debated. For instance, the analysis of Cinnamomum kanehirae genome suggested a sister relationship of Magnoliids and eudicots to the exclusion of monocots, while the genomes of Litriodendron chinense and Persoa americana suggested Magnoliids as a sister group to the clade consisting of both eudicots and monocots. Still, some other studies, amongst those focused on organellar genes and a limited number of nuclear genes, support a sister relationship between Magnoliids and monocots, to the exclusion of eudicots. The often-conflicting evolutionary relationships also reflect the morphological complexities among monocots, eudicots, and Magnoliids. For example, the spiral floral phyllotaxis is present in Magnoliids and eudicots, but not in monocots; and Magnoliids and eudicots generally have carpels with one, two, or more ovules, while most monocots have more than two ovules. However, flowers are trimerous in Magnoliids and monocots but tetramerous or pentameric in eudicots. Intermediate ascidiate carpels are predominantly present in Magnoliids, which differentiates them from other angiosperm lineages.

As two species, C. kanehirae and P. americana, from the core Lauraceae (including the Lauraeae-Cinnamomeae group and Persae group) have already been sequenced, we here present a chromosome-level assembly of the genome of May Chang tree (Litsea cubeba Lour.), which is from the sister clade to C. kanehirae in the core Lauraceae. It is an important species for producing essential oils (roughly 95% terpenoid) that are widely used in perfumes, cosmetics, and medicine all over the world. Further, to revisit the phylogenetic position of Magnoliids relative to eudicots and monocots and to study the evolutionary relationships within the Lauraceae, we sequence the genomes of 47 species of 20 genera in Lauraceae at a low coverage. Also, to uncover the molecular basis for the various floral features and the biosynthesis of scents in Lauraceae, we analyze mixed-tissue and flower bud transcriptomes for 23 species of 16 genera in the Lauraceae family, following by further functional verifications using transient overexpression and enzyme activity assay.

Results
Genome sequencing and annotation. L. cubeba has a diploid genome (2n = 24) with an estimated haploid genome size of 1370.14 Mb. The genome was initially assembled with 155.64× sequencing reads from the PacBio platform. The assembled contigs were subsequently linked into 1514 scaffolds with 10x genomics barcoded reads (Supplementary Note 1 and Supplementary Table 1). We obtained an initial genome assembly with 1514 scaffolds covering 1325.69 Mb, with a contig N50 value of 607.34 kb (Table 2). Further scaffolding was done based on 292.17 Gb reads from a sequencing library of Genome-wide Chromosome Conformation Capture (Hi-C). We were able to anchor a total of 1018 scaffolds covering 1253.47 Mb (94.56%) of the assembled genome into 12 pseudochromosomes (Supplementary Figs. 2c, 3, and Supplementary Table 3). To confirm the completeness of the assembly, we performed CEGMA, BUSCO assessments, and used mRNA sequences of L. cubeba and found the completeness of the genome to be 95.97% (Supplementary Table 4), 88.4% (Supplementary Table 5), and 97% (Supplementary Table 6), respectively. A combination of homolog-based comparisons and structure-based analyses resulted in an annotation of 735 Mb transposable elements (TEs), representing 55.47% of the L. cubeba genome (Supplementary Table 7), which is between that of C. kanehirae (~48% in a 730.7 Mb genome) and L. chinense (~62% in a 1742.4 Mb genome) (Supplementary Table 8). Long terminal repeats (LTRs) are the predominant TEs in the genome of L. cubeba, which represent 47.64% (631 Mb) of the whole genome. Both L. cubeba and L. chinense have a larger genome size than that of C. kanehirae, and they both contain higher content of LTR/gypsy and copia elements (45.31%) than that of the C. kanehirae genome (16.50%). Hence, it suggests that LTR/gypsy and copia elements contribute most to the expansions of the L. cubeba and L. chinense genomes (Supplementary Table 8).

A high-confidence set of 31,329 protein-coding genes were predicted in the L. cubeba genome, of which 29,262 (93.4%) and 27,753 (88.59%) were supported by transcriptome data and protein homologs, respectively (Supplementary Fig. 4a and Supplementary Table 9). A total of 29,651 (94.6%) predicted protein-coding genes were functionally annotated (Supplementary Fig. 4a and Supplementary Table 10) and 30,314 (91.3%) of the genes could be located on the 12 pseudochromosomes. In addition, 1284 (89.2%) of the 1440 protein-coding genes in the BUSCO plant set were predicted in the L. cubeba genome (Supplementary Table 5).

We then compared the genomes of 26 plant species to obtain gene families that are significantly expanded in Lauraceae or that are unique to Lauraceae (Supplementary Fig. 4b, c and Supplementary Table 11). Kyoto Encyclopedia of Genes and Genomes (KEGG) and Gene Ontology (GO) enrichment analyses found that the significantly expanded gene families are especially enriched in the KEGG pathways of monoterpoid biosynthesis, biosynthesis of secondary metabolites, and metabolic (Supplementary Table 12) and in the GO terms of TPS activity, transferase activity, and catalytic activity (Supplementary Table 13). Many monoterpene synthase (TPS-b) genes are included in the above enriched KEGG pathways and GO terms, in line with the roles of TPS-b in the biosynthesis of specific scents (mainly monoterpene) in Lauraceae. The enrichment analyses showed that the 711 unique Lauraceae gene families are specifically enriched in the KEGG pathways of plant hormone signal transduction and circadian rhythm—plant (Supplementary Table 14) and in the GO terms of regulation of cellular metabolic and organic cyclic compound metabolic processes (Supplementary Table 15). Hormone-related transcriptional factors are over-presented in the unique gene families to Lauraceae, for example, ABCSCISIC ACID-SENSITIVE 5 (ABIS) and ethylene-responsive transcription factor ERF098. Furthermore, the species-specific gene families of L. cubeba are significantly enriched in the KEGG pathways of biosynthesis of terpenoids and steroids and nitrogen metabolism, and the gene families under significant expansion in L. cubeba include many members from the ABC transporter C family, which is generally involved in the membrane transport of the secondary metabolism. It is interesting to notice that the TPS and ABC transporter members form gene clusters on chromosomes 8 and 12 (Supplementary Fig. 5).
The phylogenetic position of Magnoliids among angiosperm. Laurales are an order of Magnoliids, whose evolutionary position, mainly with respect to eudicots and monocots, is still the object of contention. On the basis of the 160 single-copy gene families derived from 19 eudicots, 8 monocots, 4 Magnoliids, and 3 outgroup species (Amborella trichopoda, Ginkgo biloba, and Anthoceros punctatus), we constructed phylogenetic trees from the concatenated sequence alignments of both nucleotide and amino acid sequences (Fig. 1a, c, left side). In these analyses, Magnoliids were found as a sister group to eudicots after their common ancestor diverged from monocots, which agrees with a previous study using the C. kanehirae genome. To reduce the possibility of long branch attraction in our phylogenetic analysis, we conducted another phylogenomic analysis without Gramineae species and obtained the same topology (Supplementary Figs. 6 and 7).

Because incomplete lineage sorting (ILS) may play a role in confounding resolution of early-diverging branches within angiosperms, such as the divergence of Magnoliids, eudicots, and monocots, we further conducted the multi-species coalescent (MSC)-based phylogenomic analyses using ASTRAL by considering each gene tree from the 160 single-copy gene families separately (Fig. 1a, c, right side). The MSC-based phylogeny using nucleotides (Fig. 1a, right side) again supports a sister group relationship between Magnoliids and eudicots, to the exclusion of monocots. However, the MSC-based tree using amino acids (Fig. 1c, right side) suggests Magnoliids to form a sister group with monocots, after their divergence from eudicots. To evaluate the discordance of gene trees in our single-copy gene data set, we used the Q value in ASTRAL to display the percentages of gene trees in support of the main topology (q1), and the first (q2) and second (q3) alternative topologies (Fig. 1b, d). For example, the majority of gene trees inferred by both nucleotide and amino acid sequences support Amborellales being a sister group to other angiosperms as the main topology (q1), while there are few gene trees that support either monocots (q2) or eudicots (q3) being the sister group to other angiosperms, respectively (I in Fig. 1b, d). In contrast, the branching order for Magnoliids, monocots, and eudicots displays a high level of discordance among the
single-copy gene trees, with two nearly equally supported (and one slightly less supported) topologies in both nucleotide and amino acid sequences-based analyses (II in Fig 1b–II, d-II).

Other discordances among the single-copy gene trees analyzed with ASTRAL concerned the phylogenetic position of *Vitis vinifera* and the phylogenetic position of *P. americana* (left side in Fig 1b, d). All phylogenomic analyses focusing on Lauraceae species support a sister relationship of *Litsea* and *Cinnamomum* (right side in Fig 1b, d).

Whole-genome duplications in Laurales. Genome collinearity and paralog age distributions all show indications of two ancient whole-genome duplication (WGD) events for *L. cubeba*. Intra-genomic analysis of gene order reveals collinear regions with up to five (but mostly two to four) paralogous segments (Supplementary Table 22 and Supplementary Fig. 8), while age distributions of synonymous substitutions per synonymous site (*Ks*) for all paralogous genes (paranome), as well as duplicates retained in collinear regions (anchor pairs) both show two signature peaks for WGD events with a recent peak at *Ks* = 0.5 and a more ancient peak at *Ks* = 0.8 (Fig. 2a, b). Similarly, previously sequenced genomes (of *C. kanehirae* and *P. americana*) and transcriptomes (from this study and 1KP) of Lauraceae also show two signature peaks in their paranome *Ks* distributions, except for *Cassuya filiformis* (Supplementary Fig. 9), for which only one signature peak could be identified. WGD analyses using the *C. kanehirae* genome suggested that the recent WGD in *C. kanehirae* is shared by all the Lauraceae species except *C. filiformis*, while the ancient WGD seems shared by Laurales and Magnoliidae, i.e., the two clades that form a sister group in the Magnoliid clade. Also, the analysis of the genome of *L. chinense*, another species in the order of Magnoliidae, supported a WGD prior to the divergence between Laurales and Magnoliidae.

Our analyses of the transcriptomes of non-Lauraceae Lauralean species, however, found that although some of these species have only one WGD peak in their paranome *Ks* distributions, others, such as *Peumus boldus*, *Laurelia sempervirens*, *Gomortega keule*, and *Chimonanthus praecox*, have two such peaks (Supplementary Fig. 9). Specifically, compared with those in *L. cubeba*, the *Ks* values of the two WGD peaks are larger in *C. praecox* and smaller in the other three species, suggesting that the signature peaks in these species may result from either different WGD events or from various substitution rates for duplicates retained following the same WGD events. Indeed, the *Ks* distributions of one-to-one orthologs identified between *V. vinifera* and species from Laurales and Magnoliidae show different *Ks* peaks for the divergence event between *V. vinifera* and Magnoliidae, indicating different substitution rates within Laurales (Supplementary Fig. 10). In short, our results provide evidence of two WGD events not only in the Lauraceae species but also in some non-Lauraceae species in the Laurales order.

To better position the two WGD events identified in the *L. cubeba* genome in the lineage of Laurales, we compared the anchor-pair *Ks* distribution of *L. cubeba* with the orthologous *Ks* distributions (Fig. 2b): (1) between *L. cubeba* and *Dehassia hainanensis*; *G. keule*, and *C. praecox* to represent the divergence of different lineages in Laurales (Fig. 2c); (2) between *L. cubeba* and *L. chinense* to represent the divergence between Laurales and Magnoliidae; and (3) between *L. cubeba* and *V. vinifera* to represent the divergence between Magnoliidae and eudicots. Both the analysis of *Ks* distributions and relative rate tests to correct for different substitution rates in different species of Laurales (Supplementary Note 2) suggest that the ancient *L. cubeba* WGD has occurred shortly before the divergence of Laurales and Magnoliidae, while the recent WGD has occurred before the divergence of Lauraceae but closely following the divergence of the lineage including *C. praecox* and the lineage including *G. keule* (Fig. 2b, c). Some species, such as *L. sempervirens*, *G. keule*, and *C. praecox*, have not experienced the recent WGD identified in *L. cubeba*, but also show two signature peaks for WGDs in their paranome *Ks* distributions (Supplementary Fig. 9). Considering *Ks* peak values (Supplementary Note 2), we infer independent WGDs in three different lineages of Laurales: one in the lineage leading to *C. praecox* and *Idiopterus australiensis*; one in the lineage leading to *L. sempervirens* and *G. keule*; and another in the lineage, including Lauraceae, *P. boldus*, and possibly *G. americanus* (Fig. 2c). Interestingly, *C. filiformis*, an obligate parasitic plant in the Lauraceae, and the one with the highest substitution rate in our analysis (Supplementary Fig. 10), show a *Ks* peak that represents a lineage-specific WGD event after its divergence from other Lauraceae species (Supplementary Fig. 9 and Fig. 2c). However, we propose that *C. filiformis* shares the same WGD history as *L. cubeba* and the other Lauraceae, but draws a different picture because of its accelerated substitution rate responsible for diminishing the signature peaks for the two WGDs in its paranome *Ks* distribution.

Lauralean species must have experienced rapid radiation over ~3 million years. Interestingly, the younger WGD peaks in Laurales seem to coincide with such a period (the right-hand tree in Fig. 2c), which could imply that these WGD events might even have facilitated the rapid radiation of the early Lauraceae species. On the other hand, it cannot be ruled that there has been only one WGD event that has occurred shortly before the rapid radiation of Laurales. Under such scenario, our observation of three independent WGDs could be explained by one single WGD that has occurred just before the divergence of Lauraceae followed by independent diploidizations in the three Lauraceous lineages during species radiation, with similarity to the process described in the “lineage-specific ohnologue resolution” model.

The evolution of floral structures in Lauraceae. To investigate the evolution of floral structures in Lauraceae, we first inferred the phylogenetic relationships within Lauraceae using both the concatenated and MSC approaches based on single-copy genes identified from the transcriptomes of 22 species representing 16 genera (Fig. 3a, Supplementary Notes 3 and 4, Supplementary Fig. 11, and Supplementary Table 23). We also obtained a plastid phylogeny based on the reconstructed plastid genomes from 27 species representing 19 genera in Lauraceae (Supplementary Note 5 Supplementary Tables 24 and 25). Phylogenetic trees reconstructed from concatenated sequence alignments had similar topologies than the MSC trees, except for the position of *Lindera* and *Laurus* (Supplementary Fig. 12). Comparing the nuclear and plastid trees, however, we identified notable differences for some genera in Lauraceae, such as *Lindera*, *Laurus*, *Nothaphoebe*, *Phoebe*, *Dehaasia*, *Persea*, and *Alseodaphne* (Supplementary Note 6). ASTRAL analysis also shows phylogenetic discordance among gene trees for the discordant nodes between the nuclear tree and plastid tree (Supplementary Fig. 12), indicating a complicated evolutionary history of Lauraceae. Specifically, *Cryptocarya* is the sister group to other Lauraceae species in the plastid tree, while in both the concatenated and MSC trees based on nuclear genes, *Cassuya* is a sister to other Lauraceous species. Similar differences have been reported in previous studies, at least in our ASTRAL analysis; strong support is given to the sister relationship between *Cassuya* and other Lauraceous species with few discordant gene trees with respect to *Cassuya* (Supplementary Note 6, Supplementary Fig. 13).

Generally, the inflorescences in Lauraceae are panicles, spikes, racemes, pseudo-umbels, and umbels. These characteristics of...
inflorescences are of importance to the classification of the Lauraceae family (Fig. 3b). To investigate the genes that are potentially involved in the evolution of inflorescences, we considered the transcriptomes of flower buds for 21 different species (Supplementary Note 7 and Supplementary Table 26) and phylogeny of Lauraceae inferred by MrBayes were conducted (Fig. 3a). In particular, we focused on the FUWA genes in 13 genera, because FUWA has been reported to play an essential role in determining panicle architecture in rice, sorghum, and maize. A phylogenetic tree based on the orthologs of FUWA in different Lauraceae species (Supplementary Note 8) seems consistent with the evolution of inflorescences (Fig. 3a, b, and c). The Cassytha and Cryptocarya group, which diverged earlier than other Lauraceae lineages, have spike and spikelike panicles, respectively, which are usually referred to as irregular panicles. Subsequently, regular panicles and umbels are present in other Lauraceae species. For example, cymose panicles appear in the Alseodaphne-Phoebe clade, pseudo-umbels appear in Sassafras, and umbels appear in the Litsea-Laurus clade. Consistently, the analyses of domain architectures of the FUWA gene indicate that the gene contains two conserved NHL domains in the early-diverging lineages of the Cryptocarya Group and Cassytha and three NHL domains in other Lauraceae species (Fig. 3c). A similar pattern has also been observed in Lauraceae for involucres. In Lauraceae, genera with panicles and racemes have no involucres, while Sassafras with pseudo-umbels has bracts linear to filamentous, and the Litsea-Laurus clade with umbels has an obvious involucres. The inflorescences morphological differentiation could be related to the geographic distribution of Lauraceae. The Cryptocarya Group and Cassytha are found in the Southern Hemisphere, while the other clades are mainly distributed in the amphi-Pacific or Asian areas.

Fig. 2 Whole-genome duplications in Laurales. a $K_S$ age distribution for the whole paralome of $L$. cubea. Two $K_S$ peaks are shown by dotted lines at $K_S \approx 0.5$ and 0.8 falling in two $K_S$ ranges highlighted by two gray rectangles in the background from 0.3 to 0.645 and from 0.645 to 1.1, respectively. b $K_S$ age distributions for anchor pairs of $L$. cubea (dark gray histogram and line; peaks represent WGD events) and for one-to-one orthologs between $L$. cubea and selected Lauralean species and V. vinifera (colored filled curves of kernel-density estimates; a peak represents a species divergence event). The arrows in different colors indicate under- (to the left) and overestimations (to the right) of the divergence events and point to the $K_S$ values after corrections of different substitution rates in the three comparisons based on that in $L$. cubea (see Methods). c The phylogeny of Laurales and Magnoliales with branch lengths in $K_S$ units (left) and in absolute divergence time (right). The tree topology and absolute divergence time were retrieved. The $K_S$ ages and their 95% confidence intervals (CIs) for WGDs identified from the whole paralome (Supplementary Fig. 9) are shown in dots and rectangles, respectively, on the left phylogeny. Without considering species with only one $K_S$ peak in their $K_S$ distributions of paralogs, the blue and green rectangles highlight the ranges of 95% CIs of WGDs for the older peaks and the younger peaks, respectively. The red, light blue, and yellow rectangles show the ranges of 95% CIs for three independent WGD events in different lineages of Laurales. Correspondingly, the red, light blue, and yellow bars illustrate the independent WGD events on the right phylogenetic tree with absolute divergence time. The three WGD events occurred at about the same time of the radiation of Lauralean species within -3 million years. In addition, the green bar denotes a lineage-specific WGD event in C. filiformis and the blue bar denotes the WGD event before the divergence of Laurales and Magnoliales.
The perianth tube from the perianth tube encapsulated in fruits. Fl tubes are indistinct, short, and campanulate, Lauracea clades exhibit higher level of expression in the (Supplementary Note 9 and Fig. 3c, f).

Perianth tubes are campanulate, short to nearly absent in the Lauraceae and these species have perianth tubes turbinate or suburceolate present in Lauraceae species. Perianth tubes are campanulate, short to nearly absent in the Lauraceae and these species have perianth tubes turbinate or suburceolate present in Lauraceae species.

The most recent common ancestor of Laurales was a tree with actinomorphic and bisexual flowers. Extant Lauraceae species include both bisexual (dioecious) and unisexual (monoecious) species (Fig. 3d and Supplementary Fig. 1). To identify the genes involved in the sexual determination in Lauraceae, we produced transcriptional expression levels of TGA10 in male flowers in Lauraceae. TGA10 exhibited a higher level of expression in the flower buds of the basic group lineage (Cryptocarya group), which presented an abscession of the perianth tube from the perianth tube encapsulated in fruits.

The phylogenetic tree of FUWA homologs in different Lauraceae species (Fig. 3e). TGA10 has higher transcriptional expression level in male flowers than that in female flowers from eight unisexual species representing four genera, and TGA10 also has higher expression level in male flowers comparing with that in bisexual flowers from nine bisexual species representing six genera of Lauraceae. Source data underlying a, e–g are provided as a Source Data file.
b bisexual flowers from dioecious species in Lauraceae (see "Methods," Supplementary Note 10 and Fig. 3d, g). Our results hence suggest that TGA10 is involved in male flower development, which is consistent with studies that have found that TGA10 is required for anther development.39 Moreover, a hypothesized protein (Lcu01G_02292) may also have contributed to sexual determination in Lauraceae, considering their differential expression patterns in bisexual and unisexual flowers in Lauraceae (Supplementary Fig. 14). We also compared the MADS-box genes in the sequenced Lauraceae species and a few other angiosperms (Supplementary Note 11, Supplementary Fig. 15, and Supplementary Table 27). Notably, we found that SOC1-like genes are expanded in both L. cubeba (seven members of SOC1) (Supplementary Table 28) and C. kanchirae (eight members of SOC1)12. Consistent with the expanded SOC1 clade, the SVP clade is also expanded and it counts five members in L. cubeba (Supplementary Fig. 15). It has been reported that the interaction of SOC1 and AGL24 from the SVP clade integrates flowering signals in Arabidopsis.40 Both the expanded SOC1 and SVP clades could be involved in complex flowering regulation networks and could relate to differential regulation of dioecious plant flowering.

Mono-TPS involved in volatiles production in Lauraceae. The essential oils produced by Lauraceae are widely used commercially, and contain a variety of components (Supplementary Table 29), such as geranial, neral, limonene, and linalool7,12,19,20. TPSs are the rate-limiting enzymes in the production of such terpenoids5,41 (Fig. 4). The present gene family analysis suggests that the TPS-b gene clade is significantly expanded in Lauraceae (Supplementary Tables 12 and 13). We hence identified all the TPS genes in Lauraceae by combining the data for the L. cubeba genome and the transcriptome data for 23 species, from 16 genera, in the Lauraceae family (Supplementary Tables 30 and 31). Lauraceae species with a high percentage content of essential oil had larger numbers of TPS-b members (Supplementary Tables 30 and 31), for example, L. cubeba possessed 24 TPS-b genes in (3–7%, the percentage of essential oil in fresh fruit), Cinnamomum verum possessed 12 TPS-b genes (1.32–2.13%, the percentage of essential oil in fresh leaves), Machilus salicina possessed 13 TPS-b genes (1.05%, the percentage of essential oil in fresh leaves), and P. americana possessed 17 TPS-b genes (1%, the percentage of essential oil in fresh ripe fruit)14 (Supplementary Tables 30 and 31).

We analyzed the first key enzyme in the scent biosynthetic pathway, namely 1-deoxyxylulose 5-phosphate synthase (DXS), which has three clades (Supplementary Fig. 16). The members in the clade B are expanded across Litsaea, Beilschmiedia, and Sassafras (Supplementary Note 12 and Supplementary Fig. 16); as a result, Lauraceae produce high levels of terpenoids. LcuDXS3-5 belongs to clade B and exhibits very high expression in fruits according to the transcriptome data12 (Fig. 4). Furthermore, transient overexpression of LcuDXS3 in L. cubeba could induce the increase of several components of monoterpenes and sesquiterpenes (Supplementary Note 12 and Supplementary Fig. 17).

To further investigate the members of TPS-b and TPS-g involved in terpenoid biosynthesis, additional expression and functional verification studies were conducted in L. cubeba. Among the 52 full-length TPS genes in L. cubeba, 27 were predicted as monoterpenoid synthase genes, 17 as sesquiterpene synthase genes, and the remaining 8 as diterpene synthase genes (Fig. 4 and Supplementary Tables 32–34). Tandem duplication (Fig. 5a and Supplementary Fig. 5) events have contributed to the expansion of the TPS-b subfamilies. Both Illumina transcriptome sequencing data (Fig. 4) and qRT-PCR verification showed (Supplementary Fig. 17) that LcuTPS22 specifically accumulated in leaves. Transient overexpression and enzyme activity assay both demonstrated that LcuTPS22 catalyzed the accumulation of α-pinene, β-pinene, eucalyptol, camphene, eucalyptol, and camphor, which are the main volatile components of the leaves of Lauraceae species (Fig. 5). In addition, LcuTPS18, 19, 20, 25, 26, and 42 were all highly expressed in the L. cubeba fruits (Fig. 4 and Supplementary Fig. 17). Transient overexpression and enzyme activity assay also indicated that LcuTPS42 catalyzed the biosynthesis of linalool, phellandrene, and geraniol, which are the main components of the specific scents in Lauraceae (Fig. 5 and Supplementary Fig. 18).

Besides the TPS-b gene families, other genes may also function as mediators in scent biosynthesis in L. cubeba. For example, plant hormone signal transduction enrichment of gene families is unique to Lauraceae; therefore, we investigated the endogenous hormone content and found that abscisic acid (ABA) had a unique peak close to that of the biosynthesized monoterpene in L. cubeba (Supplementary Fig. 19a). Correspondingly, the treatment of L. cubeba leaves with ABA induced an increase in both the level of monoterpene (Supplementary Fig. 19b) and the expression of LcuTPS22 (Supplementary Fig. 19c). In summary, our results provide insights into the candidate genes involved in scent production in the Lauraceae family. Further studies are, however, required to elucidate the mechanisms underlying the regulation of these genes in the scent biosynthetic pathways in Lauraceae.

Discussion

It seemed that the evolutionary relationships between Magnoliids, monocots, and eudicots as still unresolved, since our ASTRAL analyses suggest the possible ILS during the rapid divergence of early mesangiosperms29. ILS is a result of polymorphic alleles in the ancestral populations. Despite nucleotide polymorphisms, prevalent copy number variations could also exist in the ancestral populations and exacerbate the effects of ILS, as suggested by gene count data used to infer the phylogenetic position of Magnoliids in a previous study on the P. americana genome14. Besides sequence data, approaches based on synteny data could perhaps provide additional evidence with respect to the evolutionary relationship of Magnoliids. For example, utilizing sequence dissimilarities of orthologous genes located on orthologous synteny blocks, synteny-based phylogenetic analyses for P. americana supported Magnoliids as the sister group to monocots and eudicots14. Recent analyses by some of us13, considering phylogenies based on the relative gene order using synteny network data, rather than gene sequence similarities, suggested a sister group relationship between Magnoliids and monocots, thereby supporting the MSC (ASTRAL) tree based on amino acid sequence alignments (Fig. 1c).

The results of the present analyses of the key enzymes involved in monoterpene biosynthesis pathway would hence suggest that the duplications of DXS and TPS gene families may have led to the separation of biological features in terpenoid production9,44, and gene overexpression may enhance the production of main components in terpene (Fig. 5). Therefore, we propose that gene family sizes and regulation of gene expression both contribute to the accumulation of terpenoid in L. cubeba. As reported in a recent publication, following expansion of the TPS gene family, gene cluster formation, gene functional differentiation, and gene regulation divergence all could contribute to the variations in terpene production and concentration among individual species45. In addition, new functions gained by recently duplicated TPS genes may be correlated with recently evolved terpene compounds that are capable of defending plants against biotic and abiotic stresses46.
In summary, the *L. cubeba* genome provides a valuable resource for elucidating the Lauraceae evolution toolkit. Most of the present phylogenetic analyses suggest a sister group relationship of Magnoliids and eudicots, after the divergence of their common ancestor from monocots. However, the exact evolutionary relationships between Magnoliids, monocots, and dicots remain to be solved because topological conflict suggests substantial ILS in the (short) branches separating these three groups. Phylogenetic inference also suggests that the obligatory parasitic species *Cassytha* is sister to the other Lauraceae. In the *L. cubeba* genome, remnants of two ancient WGD events could be detected. In addition, comparative and functional analyses showed that TPS-b genes were significantly expanded and responsible for terpenoid biosynthesis in Lauraceae. In conclusion, our data offer insight into the genetic diversity and evolution of Laurales—and the scents they produce—and provide a stronger understanding of the evolution and diversification of Lauraceae.
Fig. 5 Phylogeny and functional verification of LcuTPSs. a Phylogeny of TPSs. Putative full-length TPS proteins (>200 amino acids in length) identified in *L. cubeba* (Supplementary Table 32) and 10 other sequenced plant genomes (Supplementary Table 33) were subjected to phylogenetic analysis. TPS subfamilies are shown along the circumference of the circle. b Transient overexpression of LcuTPS19 in *Nicotiana benthamiana* leaves. After infiltration, the plants were grown for 2 days and the presence or concentration of the monoterpenes was detected using GC-MS analysis. Data represent the mean ± SDs of three biological replicates. c Identification of enzymatic products after incubating recombinant LcuTPSs proteins with geranyl diphosphate. The volatile terpenes were further analyzed by GC-MS analysis comparison with authentic standards (Supplementary Fig. 1B). Source data underlying a, b are provided as a Source Data file.

**Methods**

**Sample preparation and sequencing.** For genome sequencing, we collected tissues from *L. cubeba* in Zhejiang Province (Supplementary Note 1), China, with a karyotype of 2n = 24 and with uniform and small chromosomes (Supplementary Fig. 2a). Genomic DNA was isolated from the buds of *L. cubeba*, and at least 10 μg of sheared DNA was taken. SMRTbell template preparation involved DNA concentration, damage repair, end repair, ligation of hairpin adapters, and template purification, undertaken using AMPure PB Magnetic Beads (Pacific Biosciences). Finally, we carried out 20 kb single-molecule real-time DNA sequencing using PacBio to sequence a DNA library on the PacBio Sequel platform, yielding ~213 Gb PacBio reads (read quality ≥ 0.80 and mean read length ≥ 7 kb) (Supplementary Table 1).

**Genome assembly and assessment.** The assembly of *L. cubeba* genome was conducted using PacBio and 10× Genomics Linked-Reads. De novo assembly of the PacBio reads was performed using FALCON (https://github.com/PacificBiosciences/FALCON/) with single-molecule, real-time sequencing. Briefly, the longest 60× coverage of subreads were selected as seeds to do error correction with parameters “--output_multi --min_idt 0.70 --min_cov 4 -- max_n_read 300.” The corrected reads were then aligned to each other to construct string graphs with parameters “--length_cutoff_pr 11000.” The graph was further filtered with parameters “--max_diff 70 --max_cov 70 --min_cov 3” and contigs were finally generated according to these graphs. The primary contigs were then polished using Quiver by aligning SMRT reads. The total length of this assembly was 1700.7 Mb, with a contig N50 of 460.7 kb. The total length of this assembly was 1700.7 Mb, with a contig N50 of 460.7 kb. The total length of this assembly was 1700.7 Mb, with a contig N50 of 460.7 kb. The assembly of *L. cubeba* genome was duplicated in the assembly. We, therefore, undertook a redundancy filtering step for the assembly. The removal of genome hybrids was achieved by a purge of haplotigs, which provided a pipeline to the reassignment of allelic contigs. Briefly, the pipeline first identified putative heterozygous contigs through read-depth analysis. Contigs with a high proportion of bases within the 0.5× read-depth peak were assigned as putative heterozygous contigs. These putative heterozygous contigs were then subject to a sequence alignment to identify its allelic companion.
contig. Then the identified haplotags were removed from the assembly iteratively. We attempted several cutoffs for the pipeline, then selected a genome version that was balanced between redundancy and integrity. The total length of the filtered genome assembly was 1315.8 MB, with a contig N50 of 603.7 kb. The filtered assembly was then connected by 10x genomics data. We used the BWA-ME algorithm (Toward better understanding of artifacts in variant calling from high-coverage samples) to align the 143.28 GB 10x genomics data (Supplementary Table 1) by the default setting and the scaffolding was performed by FragScaf (A hybrid approach for de novo human genome sequence assembly and phasing) using the alignment file as the input. We selected on the parameters of f = 1.25 and u = 2 to achieve a relatively conservative assembly and minimize the introduction of scaffolding errors. After that, we used PBelly (Mind the gap: upgrading genomes with PacBio long-read sequencing technology) software to fill gaps with PacBio data. The options were -minMatch 8 -spTupleSize 8 -minPctIdentity 75 -best1 nCandigets 10 -maxScore 500 -nproc 13 -noSplitSubreads. In order to get enough corrected genome sequences, we used Pilon (v1.18) with default settings to do the second round of error correction. For the input BAM file, we used BWA (Aligning sequence reads, clone sequences and assembly contigs with BWA-MEM) to align total 359.77 Gb Illumina short reads (Supplementary Table 1) to the assembly and used SAMTOOLS (The Sequence Alignment/Map format and SAMtools) to sort and index the BAM file. Finally, we obtained a genome with a contig N50 size of 607.34 kb and a scaffold N50 size of 1.76 Mb. The total length of this genome version was 1325.59 Mb, and it contained 0.90% Ns (Supplementary Table 2).

To confirm the quality of the genome assembly, we performed a BUSCO (http://busco.ezlab.org/) assessment using 1440 single-copy orthologous genes (Supplementary Table 5), and we found a genome completeness value of 88.4%. To confirm the high quality of the assembly, we found available mRNA sequences to the assembled genome using BLAST software (http://genome.ucsc.edu/) and confirmed that 97.91% were supported by transcription data, with a sequence coverage >50% (Supplementary Table 6).

Hi-C library construction and assembly of the chromosome. For Hi-C libraries construction, 3 g seedlings were crosslinked with 40 ml 2% formaldehyde solution at room temperature for 20 min in a vacuum. Glycerin (2.5 M) was added to quench the crosslinking reaction. After fixation, 0.5% of fixed tissue was ground with liquid nitrogen for the first round of library preparation. The extracted nuclei were resuspended with 50 μl 0.5% SDS followed by incubation at 62 °C for 10 min, and then SDS molecules were quenched by adding 25 μl 10% Triton X-100 and incubated at 4 °C for 5 min. The resulting digestion in the nucleus, DNA was digested with four-cutter restriction enzyme DpnII and incubated at 37 °C overnight. The DpnII enzyme was inactivated at 62 °C for 20 min. The cohesin ends were filled and marked with biotin-labeled dCTP and dCAP, dTTP, and dGTP by Klenow and incubated at 37 °C for 30 min. The proximal chromatin DNA was produced in this study, and each library produced about 400 million 150-nucleotide reads, following the manufacturer instructions (Illumina). Two transposable elements and repetitive DNA. TE s contribute to genome dynamism both in size and in structure, through insertion and eventual loss. Genomic scaffolds were masked using RepeatMasker (http://www.repeatmasker.org/) on the default settings after employing RepeatModeler/RepeatScout/Piler/LTR finder software with RepBase database prediction. Meanwhile, the TE s in the genome were identified through RepeatMasker soft mask annotation, using the RepBase database.

Predictions of genes and noncoding RNA. To generate gene models with high confidence, we applied a gene-annotation framework by combining evidence drawn from spliced transcripts of RNA-seq ab initio gene predictors and protein evidence drawn from orthologous proteins of closely related and model plant species. The detailed procedure was referred to Supplementary Note 13 and finally 31,329 protein-coding genes were predicted (Supplementary Table 9). We then performed functional assignments of protein-coding sequences of L. cubeba genes to the public protein databases KEGG (http://www.genome.jp/kegg/), SwissProt (http://www.uniprot.org/), TrEMBL (http://www.uniprot.org/), and InterProScan v5.11-51.0 (http://www.ebi.ac.uk/interpro/). In this way, we generated functional assignments for 94.6% (29,651/31,329) of the available L. cubeba genome (Supplementary Table 10).

Noncoding RNA was determined using structural features and homology assignments. rRNA was determined via BLAST to rRNA sequencing of other species, using the high levels of conservation in species. tRNA was identified using tRNAscan-SE (http://lowelab.ucsc.edu/tRNAscan-SE/). In addition, other types of noncoding RNA, including miRNA and snRNA, were identified using INFERNAL to search the Pfam database (http://infernal.janelia.org/).

Ortholog detection with OrthoMCL. We downloaded genome and annotation data for *Actinidia chinensis* (GCA_003024255.1), *Annona squamosa* (GCF_001540865.1), *Arabis japonica* (TAIR 10), *Asparagus officinalis* (GCF_001870653.1), *A. trichopoda* (V1.0), *Beta vulgaris* (V1.2.2), *C. akeelaeae* (GCA_003546025.1), *Citrus sinensis* (GCF_000374153.1), *Cucumis sativus* (GCF_000004075.2), *Daucus carota* (V2.0), *G. biloba* (2019-06-04), *Gossypium raimondii* (V1.2), *Glycine soja* (V1.1)43, *Helianthus annuus* (GCF_002127325.1), *H. cinnamomea* (GCF_003183585.2), *M. acutifolius* (V2.1), *Macleaya cordata* (GCA_002174775.1), *Nelumbo nucifera* (GCF_000363518.1), *Oryza sativa* (GCA_003002515.1), *P. americana* (v2.0), *Phoenix dactylifera* (GCF_004113355.1), *Phalanenopsis equestris* (APL00000000.1), *Prunus persica* (V2.1), *Populus trichocarpa* (V3), *Solanum lycopersicum* (SL2.50), *Ricinus communis* (GCF_000156185.1), *S. purpurea* (GCF_0001981405.1), *Theobroma cacao* (V1.1), V. vinifera (V12X), and *Zea mays* (v2.1). We removed redundant gene families with open-reading frames of <200 bp and performed gene family clustering using OrthoMCL.

Gene family expansion and contraction. We measured the expansion and contraction of orthologous gene families using the software CAFE 4.2 (https://github.com/hahlab/CAFE2). On the basis of the maximum likelihood modeling of gene gain and loss, we analyzed gene families for signs of expansion or contraction (Supplementary Fig. 4c) using genome data from 26 species (Supplementary Table S2). Our KEGG enrichment analyses were conducted for unique, significantly expanded, and constructed gene families in Magnoliidae, Lauraeae, and *L. cubeba*.

Phylogenetic reconstruction. In order to identify more phylogenetic-informative sites, we screened the genome data of 26 species for common conserved gene families (Supplementary Table 11) by including the single-copy genes in at least 22 species, and two copies in the remaining 4 species. Thus, the total number for a single gene family was no more than 30. In species with two copies of a given gene family, we selected the gene with the best BLAST hits. Finally, we obtained 1201 common conserved gene families in 26 species. For the gene families that had undergone expansion and contraction and the divergent time estimation, we constructed a phylogenetic tree based on these 1201 common conserved gene families using MrBayes software with GTR+F+I model. For phylogenetic reconstruction in angiosperms, we derived 160 common single-copy gene families from BUSCO database for 34 species (Fig. 1); the phylogenetic tree was constructed based on concatenated single-copy gene family alignment and coalescent-based approaches that incorporate individual gene tree. A concatenated phylogenetic tree (Fig. 1) was inferred using MrBayes (v3.2.6) with GTR+F+I Model. For coalescent-based approaches, we used ASTRAL to combine gene trees from 160 single-copy genes, and the q value was used to account for variation among gene trees owing to ILS. For gene tree estimation, both the nucleotides and amino acids were used to reconstruct the phylogenetic trees by RAxML v.8.1.17. For coalescent approaches, we used ASTRAL and the built-in local posterior probabilities of the ASTRAL topology to refer to the tree inferred

NATURE COMMUNICATIONS | https://doi.org/10.1038/s41467-020-15493-5 | www.nature.com/naturecommunications
from 160 unbinned amino acid alignments in which branches with 33% or less support is contracted, which refers to the potential ILS.

To analyze Lauraceae with plastid genome data, we retrieved and organized Illumina-sequence transcriptomic data for various tissues (including flower buds, flowers, leaves, stems, buds, and bark) of 23 species representing 16 genera, representing the main lineage of Lauraceae and their closest relative outgroups. To identify the ages of WGDs in the K 5 value as support is contracted, which refers to the potential ILS. We assembled the plastid genomes from incorporated re-sequenced genome data, we assembled the plastid genomes from incorporated re-sequenced trees based on a similar method. To perform a phylogenetic analysis using plastid genome data, we assembled the plastid genomes from incorporated re-sequenced data of 27 species representing 19 genera of Lauraceae as well as the outgroup Calycanthus floridus (Supplementary Note 5 and Supplementary Table 24).

Identification of whole-genome duplications in Lauraceae. K 5-based age distributions for all paralogous genes (paranome) of genomes and transcriptomes in Magnoliids were constructed. Concisely, the paralogs were built by identifying gene families with the mclblast pipeline (v10-201) (micasm.org/mcl) after performing all-against-all-BLASTP search with an E value cutoff of 1 × 10 -10. Each gene family was aligned using MUSCLE (v3.8.31) 55. Then the CODEML program in the PAML package (v4.4c) 57 was used to estimate K 5 for all pairwise comparisons within a gene family. Gene families were further subdivided into subfamilies for which K 5 values between members did not exceed 5. As a gene family of n members produces n(n−1)/2 pairwise K 5 estimates for n − 1 retained duplication event, we corrected for the redundancy of K 5 values by first inferring a phylogenetic tree for each subfamily using PhyML 56 with the default settings. Then, for each duplication node in the resulting phylogenetic tree, all m K 5 estimates for a duplication between the two child clades were added to the K 5 distribution with a weight of 1/m, so that the sum of the weights of all K 5 estimates for a single duplication event was 1.

To identify synteny or collinear segments in the genome of L. cubeba, i-ADHoRe (v3.0) was used with the parameters level_2_only=FALSE, enabling the ability to detect highly degenerated collinear segments resulting from more ancient large-scale duplications (this is achieved by recursively building genomic profiles based on relatively recent collinear segments) 55. The K 5 distribution of paralogs located on collinear segments (anchor pairs) was calculated using maximum likelihood in the CODEML program of the PAML package (v4.4c) 57 3 57. The K 5-based ortholog age distributions were constructed by identifying one-to-one orthologs between species by selecting reciprocal best hits 55, followed by K 5 estimation using the CODEML program, as above. To compare different substitution rates in Magnoliids species, we compared the K 5 distributions of one-to-one orthologs identified between V. vinifera and L. cubeba and the K 5 distributions of one-to-one orthologs identified between V. vinifera and C. kanehira, P. americana, D. hainanensis, Notophoehoe cavaleriei, C. filiformis, P. boldus, G. americanus, L. sempervirens, G. keule, C. praecox, L. chisnalliana, and L. chilense. The observed substitution rates were estimated by the likelihood in the CODEML program of the PAML package (v4.4c) 57. To further place the WGD peaks identified in the genome of L. cubeba in the phylogeny of Magnoliids, we compared the anchor pair K 5 distribution of L. cubeba and the orthologous K 5 distributions between L. cubeba and D. hainanensis, G. keule, C. filiformis, C. praecox, L. chisnalliana, and V. vinifera. To quantify the differences in substitution rates among these Magnoliids species, we performed a relative rate test, using V. vinifera as an outgroup to calculate K 5 distances after the divergence between L. cubeba and each of the Magnoliids species. The K 5 distance between any two species in a relative rate test was estimated by the mode of their orthologous K 5 distribution. As the substitution rates seemed to vary considerably among the sequenced Magnoliids so far (Supplementary Fig. 8), the calculated K 5 distance for L. cubeba in each relative rate test was used to correct the orthologous K 5 peaks between L. cubeba and other Magnoliids species under the assumption that the two species have an identical substitution rate after their divergence (arrows in Fig. 2b). For example, using the K 5 distance between L. cubeba and G. keule, the K 5 distance between V. vinifera and G. keule, and the K 5 distance between V. vinifera and L. cubeba, we used a relative rate test to calculate K 5 distances to the lineage of G. keule and L. cubeba after their divergence. Then, orthologous K 5 values were corrected by twice of the K 5 distance to L. cubeba (assuming that L. cubeba and G. keule had the same substitution rate). To further place the WGD peaks identified in the paralogue K 5 distributions from other genomes and transcriptomes in Magnoliids (Supplementary Fig. 8), we built a collection of species from Laurales and L. chilense, along with A. trichopoda and G. biloba as extra outgroups (Fig. 2d), using OrthoMCL on the default settings 61. Among the identified gene families, we selected 23 single-copy gene families to estimate the branch lengths in the K 5 unit using PAML (v4.4c) 57 with the free-ratio model. The topology and absolute divergence times of the phylogenetic tree were retrieved from TimeTree. To infer the ages of WGDs in the K 5 unit as well, K 5 peaks were identified in a paralogue K 5 distribution by an R function from github.com/stas-g/findPeaks after a smooth spline was fitted to the K 5 distribution. To obtain a 95% CI for each identified K 5 peak, K 5 values of paralogues in a wide range of the estimated peak were resampled 100 times to obtain the 95% confidence interval (Supplementary Note 3 and Supplementary Table 23). We also performed phylogenetic reconstruction, we used a HomBlocks pipeline 62 to locate the collinear regions for alignment. The plastid genomes were used to construct a phylogenetic tree (Fig. 3).

Transcriptomic data and analysis in Lauraceae. For library construction, a total of 1.5 gRNA was prepared, and libraries were generated using the NEBNext Ultra II® RNA Library Prep Kit for Illumina® (NEB, USA). The index codes were put into attribute sequences for each sample. The clustering of the index-coded samples was carried out on a cbot Cluster Generation System using the TruSeq PE Cluster Kit V3-cbot-LS (Illumina). Subsequently, the libraries were sequenced on an Illumina HiSeq platform to produce paired-end reads. The raw reads were further processed using in-house Perl scripts to remove reads containing adapters, reads containing ploy-N, and low-quality reads. At the same time, Q20, Q30, and GC-content levels and sequence duplication levels of the clean data were calculated. All downstream analyses were conducted with high-quality clean data. Transcriptome assembly was accomplished using Trinity 64, with min_kmer_cov set to 2 as a default and with all other parameters set to default values. All transcriptome assemblies were further valued by a BUSCO assessment (https://busco.ezlab.org/) 23 (Supplementary Fig. 20). Protein sequences and coding sequences of the transcripts were predicted using TransDecoder (http://transdecoder.github.io). For genes with more than one transcript, the longest was taken as the unique gene and expression levels were estimated by RSEM 65. Gene (or transcript isoform) expression values were provided using the fragments per kilobase of million mapped reads method 66. To determine whether the chimeric transcripts occurred in the gene family of TPSs, we conducted a local BLAST E value <1 × 10 -9 and found that 18 transcripts from the de novo assembled transcriptome of L. cubeba were corresponded to the genome data (Supplementary Table 35).

We generated three sets of transcriptome data. First, we obtained Illumina-sequence transcriptomic data for various L. cubeba tissues to enable the L. cubeba genome assembly. The transcriptome data were mapped on to the L. cubeba genome for gene expression analysis. Second, we generated and integrated Illumina-sequence transcriptomic data for various tissues (including flower buds, flowers, leaves, stems, buds, and bark) of 23 species in 16 genera, representing the main lineage of Lauraceae and C. praecox (Supplementary Note 3 and Supplementary Table 23), and the Pacbio Iso-seq data of C. filiformis and C. praecox (Supplementary Note 4). These de novo mixed-tissue transcriptome data were used to conduct a phylogenetic analysis of Lauraceae, and we also used to annotate gene homologs, including the TPSs and DXs of this family. The gene homologs were identified using the HMmer software package. Third, to explore the genes involved in the regulation of the evolution of orthologous genes of Lauraceae, we generated transcriptomic data for flower buds in triplicate for 23 species, representing 13 genera in Lauraceae (Supplementary Note 7 and Supplementary Table 26).

The transcriptomes of flower buds were used to excavate the genes involved in flower development and sexual differentiation in Lauraceae. We screened genes that had been reported to be involved in panicle and perianth development in other species. The phylogentic trees of the candidate genes in Lauraceae were
constructed. Only the phylogenetic tree constructed by the FUWA homologs of Lauraceae was consistent with the evolutionary characteristics of inflorescences in this family, and a detailed method for the selection of FUWA in Lauraceae is given in Supplementary Note 8. The expression levels of the gene homologs in Lauraceae were compared and PTL was found to have a similar expression pattern to that during the presentation of the abscission of the perianth tube and its encapsulation in fruit (Fig. 3f and Supplementary Note 9). Moreover, the DEGs involved in the development of bisexual and unisexual flower buds of L. cubeba were analyzed based on the flower bud transcriptome data. The DEGs (fold change >2, P < 0.05) between the female and male flowers in *Litsea tinlingensis*, *Litsea rubescens*, *L. cubeba*, *Lindera megaphylla*, and *Sassafras tzumu* were selected. KEGG pathway and GO term-enrichment analyses of DEGs were subsequently conducted for each species. Interestingly, the DEGs were observed to be significantly enriched in the Plant Hormone Signal Transduction (map04075) in each species. Unsurprisingly, TAG10 and a hypothesized protein (Lcu01G_02292) in the region of 124099255–124107806 in chr1 of the *L. cubeba* genome were included in the enriched plant hormone signal transduction pathway of each of the above species, and exhibited distinctive expression (Supplementary Tables 32 and 33) and maximum likelihood phylogenetic trees. Finally, we analyzed the expression modes of TAG10 and the hypothetical protein in the transcriptome data of male, female, and bisexual flower buds in Lauraceae. The detailed method for the selection of PTL, FUWA, and TGA10 genes in Lauraceae are given in Supplementary Notes 8–10.

**TPSs identification and functional validation experiments.** To avoid missing potential TPS genes, candidate TPSs were identified from the predicted proteomes of *L. cubeba* and other Lauraceae species by pfamscan results obtained from the HMMER scan suite (http://hmmer.janelia.org/), using the Pfam profiles of PF01397 and PF03936 as queries (E value < 10⁻⁵) with a protein length over 200 amino acids ⁸. The candidate TPS genes were further inspected manually using InterProScan5 (http://www.ebi.ac.uk/interpro/) to confirm putative full-length TPS genes. A total of 52 such full-length *LcuTPS* genes were identified. Although the above criteria may result in the identification of pseudo- or partial genes, 41 of the 52 identified TPS genes were found to have more than 500 amino acids. The full-length TPSs were analyzed with ChloroP for the prediction of N-terminal plastidial targeting peptides (http://www.cbs.dtu.dk/services/ChloroP/). The analysis of the exon/intron structures of the full-length TPS genes were also conducted using GSDS (http://gds.cs.pku.edu.cn/), and the conserved motif RR(X)₆W and DXXDD were labeled (Supplementary Fig. 21). The MG2C (http://mg2c.iask.in/mg2c_v2.0/) software was used to construct gene distribution maps of *L. cubeba* chromosomes. Putative full-length TPSs (>200 amino acids in length) identified in *L. cubeba* and other sequenced plant genomes (Supplementary Tables 32 and 33) and maximum likelihood phylogenetic trees were built using CIPRES (https://www.phylo.org) with the JTT model using 1000 bootstrap replicates.

Gene function was validated in vivo and in vitro. For gene function validation in vivo, endogenous transient overexpression was performed in *L. cubeba* and tobacco (*N. benthamiana*) leaves. The empty vector and constructs containing *LcuTPS19*, *LcuTPS20*, *LcuTPS22*, *LcuTPS25*, and *LcuTPS42* were carried by *Agrobacterium* cultures and infiltrated into the leaves using a 1 mL needleless syringe. After infiltration, the plants were grown for 2 days; then, a leaf near (<5 mm) the infiltration point was collected and immediately frozen in liquid nitrogen. These samples were stored at −80 °C for subsequent analysis using liquid chromatography–mass spectrometer (LC–MS) analysis. The samples were ground and incubated at 40 °C for 30 min. The volatiles were further extracted using SPE fiber with 50/30 μm divinylbenzene/carboxen/polydimethylsiloxane (DVB/CAR/PDMS) (Supelco Co., Bellefonte, PA, USA). GC–MS analysis was conducted on an Agilent 6890N gas chromatograph coupled to a mass spectrometer (Agilent 5975B, Santa Clara, CA, USA) with a fused silica capillary column (DB-5MS) coated with polydimethylsiloxane (19091 S-433) (60 m × 0.25 mm internal diameter, 0.25 μm film thickness). The oven temperature was programmed to start at 50 °C for 2 min, and then ramped to 80 °C at a rate of 3 °C min⁻¹, followed by a second ramp to 180 °C at a rate of 5 °C min⁻¹, and a third ramp to 230 °C at a rate of 10 °C min⁻¹, finally, ramp to 250 °C at a rate of 20 °C min⁻¹. The conditions were as follows: ion source, 230 °C; electron energy, 70 eV; GC–MS interface zone, 250 °C, and a scan range of 50–500 m/z. There were three biological replicates for transient overexpression analysis. To identify the target monoterpenes, the retention time was compared with that of an authentic standard purchased from the Sigma-Aldrich, which was further validated using the NIST Mass Spectral Library. The primers are shown in Supplementary Table 36, and the details of the procedure are given in the Supplementary Note 14.

**Data availability**

A reporting summary for this article is available as a Supplementary Information file. Data supporting the findings of this work are available within the paper and its Supplementary Information files. The datasets generated and analyzed during the current study are available from the corresponding author upon request. The genome and transcriptome sequences described in this manuscript have been submitted to the National Center for Biotechnology Information (NCBI) under accession codes PRJNA568204 [https://www.ncbi.nlm.nih.gov/bioproject/PRJNA568204] (whole genome and assembly data), PRJNAS2115 [https://www.ncbi.nlm.nih.gov/bioproject/PRJNAS2115] (transcriptome data of 23 Lauraceae species), and PRJNA562080 [https://www.ncbi.nlm.nih.gov/bioproject/PRJNA562080] (low-coverage genome data of 47 Lauraceae species). The data underlying Figs. 1 a, 3 a, e–g, 4 a, b and Supplementary Figs. 6, 7, 13, 14, 15a, 16a, 17b–i, 19b, 19c, as well as Supplementary Tables 30 and 31 are provided as a Source Data file.
