Abstract

Background: Right ventricular dysfunction (RVdysf) is a predictor of poor outcome in patients with heart failure and valvular disease. The aim of this study was to evaluate the evolution and the impact of RVdysf in patients with moderate–severe functional mitral regurgitation (FMR) successfully treated with MitraClip.

Methods and results: From October 2008 to July 2014, 60 consecutive high surgical risk FMR patients were evaluated and stratified into two groups: RVdysf group (TAPSE < 16 mm and/or S’TDI < 10 cm/s, 21 patients) and No-RVdysf group (38 patients). The overall mean age of patients was 73 ± 8 (83% male). Ischemic MR etiology was present in 67%. Mean LVEF was 30 ± 10%. Overall mean time follow-up was 565 ± 310 days. The only significant difference between the two groups was a greater prevalence of stroke, ICD and use of aldosterone antagonist in RVdysf group. Acute procedural success was achieved in 90% of patients. At 6-month echo-matched analysis significant RV function improvement was observed in patients with baseline RVdysf (TAPSE 15 ± 3.0 vs. 19 ± 4.5, p = 0.007; S’TDI 7 ± 1.2 vs. 11 ± 2.8, p < 0.0001; baseline vs. 6-month, respectively). The mean improvement in the 6-min walking test was significant in both groups (120 and 143 m, RVdysf and No-RVdysf groups, respectively). At Kaplan–Meier analysis, the presence of RVdysf did not affect the outcome in terms of freedom from composite efficacy endpoint.

Conclusions: This study shows that successful MitraClip implantation in patients with FMR and concomitant right ventricular dysfunction yields significant improvement of RV function at mid-term follow-up. Further data on larger population will be required to confirm our observations.

1. Introduction

Mitrval regurgitation (MR) represents the second most common valvular disease in Europe [1]. This pathology evolves over many years, allowing the heart to adapt to a chronic volume overload, leading to significant and complex hemodynamic and structural changes. In chronic severe MR, left ventricular remodeling leads to the development of significant pulmonary hypertension in almost half of the patients [2,3]. The increase in right ventricular (RV) afterload at first induces right atrial and RV remodeling, and afterwards leads to RV dysfunction. RV dysfunction represents a strong and independent predictor of mortality in left ventricular ischemic and non-ischemic heart failure (HF) [4–10]. Alternate effects of surgical mitral valve repair or replacement on pre-existing RV dysfunction have been reported in different published series of patients [11–18]. Percutaneous mitral valve repair with MitraClip has been shown to be associated with a favorable clinical outcome and left and right ventricular reverse remodeling in high-risk patients with severe MR [19–22]. In the present study we evaluated the impact and the evolution of pre-existing RV dysfunction in high-risk functional MR (FMR) patients after successful MitraClip implantation.

2. Methods

2.1. Study population and clinical endpoints

From October 2008 to July 2014, 60 consecutive MitraClip treated patients were evaluated at San Raffaele Hospital and at EMO-GVM Centro Cuore Columbus, Milan, Italy. The MitraClip procedure was considered in patients with symptomatic severe FMR who fulfilled the echocardiographic criteria of eligibility and judged inoperable or at high surgical risk by a ‘heart team’, and had a life expectancy greater than 1 year (according to the ESC/EACTS 2012 recommendation class...
Ilb, level of evidence C). Each patient was informed regarding the possible risk and procedural benefit of MitraClip procedure and written consent was obtained for the procedure, data collection, and subsequent analysis and publication. The study was approved by the Hospital Ethics

Data are presented as absolute numbers and percentages (for categorical variables) or mean value ± SD (for continuous variables) unless otherwise specified. Student’s unpaired t-test for continuous data; Chi-square test for categorical data. AMI = acute myocardial infarction; ACE = angiotensin converting enzyme; ARB = angiotensin II receptor blocker; AST = aspartate aminotransferase; ALT = alanine transaminase; BMI = body mass index; BSA = body surface area; CABG = coronary artery bypass grafting; CCB = Calcium channel blockers; CRT D = cardiac resynchronization therapy with defibrillator; CRT-PM = cardiac resynchronization therapy without defibrillator; COPD = chronic obstructive pulmonary disease; ICD = implantable cardioverter defibrillator; NYHA = New York Heart Association; NT-pro-BNP = N-terminal protype-brain natriuretic peptide; PCI = percutaneous coronary intervention; RVdysf = reduced right ventricle ejection fraction; 6-MWT = six minutes walking test, available in 34 patients (60% of patients). Bold numbers indicate significance at p value < 0.05.

*Chronic renal failure (CRF) was defined as an estimated glomerular filtration rate (eGFR) < 60 ml/min/1.73 m².

**Severe pulmonary hypertension was defined as a pulmonary systolic pressure ≥ 60 mm Hg as estimated by doppler echocardiography.

**6-MWT = six minutes walking test, available in 34 patients (60% of patients).
Committee and no external source of funding supported this study. All patients had symptomatic moderate-to-severe or severe FMRI despite optimal medical therapy. Prior to implantation, all patients underwent coronary angiography to exclude relevant coronary artery disease necessitating revascularization. Furthermore, patients underwent trans-thoracic and transoesophageal echocardiography to quantify MR and to judge morphological suitability for MitraClip implantation. According to the EVEREST II protocol [23], acute procedural success (APS) was defined as implantation of at least one clip and post-procedural MR ≤ 2+. Advanced congestive heart failure (HF) defined patients with NYHA class III–IV in spite of maximal medical treatment and concomitant presence of LVEF > 70 mm and/or LVEF < 20% and/or NT-proBNP > 10,000 pg/ml. The transthoracic and transoesophageal echocardiograms were obtained using commercially available ultrasound diagnostic systems (Philips IE 33, Royal Philips Electronics, Amsterdam, The Netherlands, or Vivid 7 and Vivid E9, GE Medical Systems, Milwaukee, WI, USA) by two experienced investigators (MO and EA), according to current ESC/ACC guidelines [21]. Assessment of RV function was performed with the apical four-chamber and parasternal RV inflow and outflow tract views. The following quantitative conventional indices were measured: tricuspid annular plane systolic excursion (TAPSE), peak systolic velocity at the junction of the RV free wall and the tricuspid annulus, assessed with pulsed tissue Doppler imaging (‘S’TDI). Systolic pulmonary artery pressure (sPAP) was calculated from tricuspid regurgitation maximum pressure gradient by use of the modified Bernoulli equation, with the addition of an estimate of central venous pressure. Tricuspid regurgitation grade was evaluated according to a visual scale ranging from 1 to 4.

2.2. Study endpoints

The primary endpoint of this study was the echocardiographic evaluation of RV function at 6-month follow-up after successful MitraClip implantation (echo-matched analysis). Additional pre-specified secondary endpoints were: A) composite efficacy endpoint [cardiac death, hospitalizations for acute decompensated heart failure, LVAD (left ventricular assist device) implantation and need for conventional mitral valve surgery after MitraClip (up to 24-month follow-up)]; B) New York Heart Association (NYHA) heart failure class and C) 6 min walking test (6-MWT) at 6-month follow-up after MitraClip implantation. A 6 min walk test (6-MWT) was performed in eligible patients.

2.3. Mitraclip implantation procedure

The endovascular edge-to-edge mitral valve repair procedure has been previously described [23]. All procedures were performed using a 24 Fr MitraClip device using CS01 or CS02 (Abbott Vascular, Santa Clara, CA, USA). All clips were implanted under general anesthesia and fluoroscopic and transoesophageal echocardiographic control. Hemostasis was achieved by compression of the femoral vein for 5–10 min soon after figure-of-eight suture. Patients were transferred to our intermediate care unit or, if necessary, intensive care unit.

2.4. Clinical and echocardiographic follow-up

Before discharge, all patients were evaluated with NYHA class assessment, 6-MWT, NT-pro-BNP measurement and echocardiography. After MitraClip implantation, patients were prospectively followed up at 1, 6 and up to 24 months. Clinical evaluation of NYHA class, blood sampling for NT-pro-BNP, and echocardiography were performed at every follow-up visit. When feasible, a 6-MWT was performed. Three and nine patients declined to attend, respectively, 6 and 24 months clinical follow-up examination after implantation. Nevertheless, in these cases, follow-up data was obtained by telephone interviews. Echocardiography was performed in 53 eligible patients at 6-months (98%) and in 49 patients after 24-month (91%).

2.5. Statistical analysis

Continuous variables were reported as mean ± standard deviation (SD) or median (inter-quartile range, IQR) and compared with Student’s t test or Mann–Whitney or Wilcoxon tests, based on the normality (Kolmogorov–Smirnov goodness-of-fit test) of the data. Categorical variables (as frequencies or percentage) were compared with χ2 test with Yates correction for continuity or the Fisher exact test as appropriate for the available data [26]. Differences between matched baseline and 6-month follow-up echocardiographic data (primary endpoint) and NYHA class/6-MWT data (secondary endpoints) were analyzed using the matched-pair t-test or Wilcoxon signed-rank test, according to normality of distribution. Event-free survival during follow-up was evaluated according to the unadjusted Kaplan–Meier method and survival among groups was compared using log-rank test (Cox–Mantel test). Clinical follow-up was censored at the date of last follow-up or up to

LVEDD = left ventricular end diastolic diameter, LVEF = left ventricular end systolic fraction, LA vol = left atrial volume, MR = mitral regurgitation, RV = right ventricle, TR = tricuspid regurgitation, PAP = pulmonary arterial pressure, TAPSE = tricuspid annular plane systolic excursion, STDI = systolic wave with tissue Doppler imaging.

Bold numbers indicate significance at p < 0.05.
24 months follow-up (2-year), whichever came first. Data on patients who were lost to follow-up were censored at the time of the last contact. Cox proportional hazards methods were used to estimate the independent effect of multiple independent variables on the risk of composite efficacy endpoint (secondary endpoint). To avoid multicollinearity, a “low-noise model” has been researched in which each predictor variable correlate at most only minimally with the other. Selection of the variables included in the multivariate model was done with backward elimination (Wald statistic, confirmed using forward and stepwise selection) based on covariates listed in Tables 1 and 2. Only the covariates that were significantly associated with the risk of composite efficacy endpoint at univariate analysis ($p < 0.05$ for model inclusion and $p > 0.10$ for exclusion) and that considered clinically relevant were included, and the convention of limiting the number of independent variables to 1 for every 10 events was followed [27,28]. The proportional hazards assumption was checked both graphically and by hypothesis testing. Graphical examination was done using a log-cumulative hazard plot. Linearity was checked graphically using the smoothed martingale residuals from the null model plotted against the covariate variables. The results are reported as adjusted hazard ratios (HRs) with associated 95% Confidence Intervals (CI). Two-side p-values $<0.05$ were considered statistically significant. The statistical analyses were performed using SPSS 16.0.2 (SPSS Inc., Chicago, IL, USA) and NCSS 2007 (NCSS, Kaysville, UT, USA). Kaplan–Meier survival curves were generated with the use of GraphPad Prism software (version 4; GraphPad, Inc., San Diego, CA).

### 3. Results

The principal baseline characteristics of the overall population of patients with FMR (60 patients) are reported in Table 1. Briefly, the mean age of patients was $73 \pm 8$ (15% were $>80$ years old) and the majority of them were male (83%). Most patients had an increased surgical mortality risk as assessed by the logistic EuroSCORE ($27.2 \pm 20.5$) and STS score ($7.9 \pm 8.5$). 30 patients (50%) had a logistic EuroSCORE $>20$ and were thus considered very high risk patients for surgery. Ischemic FMR etiology was present in 67% of cases. 42 patients (70%) were in NYHA class III-IV. Preoperative echocardiographic features are reported

CVVH = continuous venous-venous hemofiltration; AMI = acute myocardial infarction; LOS = length of stay.
in Table 2. Mean LVEF was 30 ± 10% and 73% of cases had LVEF <35% at presentation. Of these, 10 patients (17%) had an NT-proBNP >10,000 pg/mL. In most of these cases, MitraClip procedure was the last treatment option before considering left ventricular assist devices implantation as destination therapy. According to echocardiographic diagnostic criteria, we identified 38 patients (65%) with no/mild RV dysfunction (No-RVdysf group) and 21 patients (37%) with moderate/severe RV dysfunction (RVdysf group). Between the two patients’ groups there were no significant differences in terms of clinical and echocardiographic characteristics except for history of previous stroke, implantable cardioverter-defibrillator (ICD) and use of aldosterone antagonist which were significantly more often present in RVdysf group. Tables 1 and 2.

3.1. Acute MitraClip results

Acute procedural success (APS) was achieved in 54 patients (90%), Fig. 1. Four patients had post-procedural MR >2+, in one case the procedure was interrupted because of pericardial tamponade soon after transseptal puncture requiring percutaneous drainage. One patient had retroperitoneal bleeding from femoral access site, which was managed with manual compression and urgent embolization with ethylcellulose microspheres. APS was obtained in all patients who implanted one MitraClip (23 patients), in none of patients treated with ≥3 MitraClips (5 patients). Peri-procedural complications are listed in Table 3. Thirty-day mortality rate was 5% (three deaths, all in-hospital): two cardiac-deaths (in patients with end-stage heart failure) and one non cardiac-death (acute respiratory distress syndrome in obstructive and restrictive lung disease).

3.2. Echocardiographic outcome

Echocardiographic data at baseline and at 6-month follow-up in 53 eligible patients are reported in Table 4, (one patient was missing for 6-month echo-matched analysis). Between baseline and 6-month follow-up, a persistent and significant reduction of MR grade was observed in all FMR patients and in the 2-subgroups, (Table 4 and Fig. 2, panel A). No significant differences were found in terms of LV end-diastolic and end-systolic volumes and diameter, as well as LVEF, in both groups (No-RVdysf and RVdysf). On the contrary, a significant improvement of RV function was observed in the overall population. RV function improvement was mainly driven by the cohort of patients with baseline RVdysf (TAPSE 15 ± 3.0 vs. 19 ± 4.5, p = 0.007; S’TDI 7 ± 1.2 vs. 11 ± 2.8, p < 0.0001; baseline vs. 6-month follow-up, respectively), and was observed in 79% of patients with baseline RVdysf (15/19 patients). In all patients, mean systolic pulmonary arterial pressure (sPAP) was significantly reduced at follow-up (49 ± 14 vs. 45 ± 13, baseline vs. follow-up, p = 0.039), while tricuspid regurgitation grade did not change significantly (2.1 ± 1.2 vs. 1.9 ± 1.0, p = 0.302); however, a sub-analysis including only 16 patients with moderate to severe tricuspid regurgitation (TR ≥2), showed a trend in reduction of TR grade after MitraClip (2.9 ± 0.9 vs. 2.4 ± 1.0, p = 0.08). We did not find significant differences in RV function improvement according to MR etiology (ischemic vs. non-ischemic cardiomyopathy).

3.3. Clinical follow-up

Mid-term follow-up events are listed in Table 5. The overall mean follow-up time was 565 ± 310 days (median 395 days). The duration

| RV diameter, mm       | 39 ± 9                   | 41 ± 7               | 43 ± 10    |

Bold numbers indicate significance at p value < 0.05.
of clinical follow-up was not statistically different between RVdysf and No-RVdysf groups. Significant NYHA improvement of 1 or 2 functional classes was observed in all patients and was persistent at 12-month follow-up (Fig. 3, panel A), without difference within the 2 groups (Fig. 3, panel B). The mean improvement in the 6-min walking test was significant in both groups (120 and 143 m, RVdysf and No-RVdysf groups, respectively; Fig. 4). Six patients (10%) died between the first month and the end of the sixth month after discharge: 5 cardiac deaths (4 due to refractory heart failure and 1 sudden death), 1 non-cardiac death (bowel occlusion). During follow-up, 2 cases of partial clip detachment were observed. Two patients received LVAD due to progressive heart failure (median time period after MitraClip 185 days, IQR 45–240). One case of redo-procedure was performed successfully for the patient with pericardial tamponade during the index procedure. At Kaplan–Meier and Cox-regression analysis, the presence of RV dysfunction did not affect the outcome in patients with APS (final MR ≤2) in terms of freedom from composite efficacy endpoint (47% vs. 63%, RVdysf vs. No-RVdysf, respectively, \(p = 0.567\), Fig. 5). Multivariable Cox regression analysis was used to identify clinical independent predictors of composite efficacy endpoint for all patients. The adjusted Cox proportional-hazard analysis identified advanced congestive HF and Logistic EuroSCORE \(\geq 25\) as significant independent predictors of composite efficacy endpoint (Table 6).

### 4. Discussion

This retrospective, observational, unblinded study involving high risk patients with FMR shows that: 1) successful MitraClip correction induces RV function improvement at 6-month follow-up in a sizeable proportion of patients; 2) RV dysfunction is not a predictor of unfavorable outcome.
Changes in left ventricle function. As a matter of fact, in chronic MR for the right ventricle and then for LV. A longer follow up could show than left ventricle is, because of their anatomical structures. It is conceivable that a reduction in volume overload could be initially beneficial for the right ventricle and then for LV. A longer follow up could show changes in left ventricle function. As a matter of fact, in chronic MR and LV dysfunction, subclinical LV damage could be present well before the appearance of LV function impairment [36,37]. Similarly, irreversible myocardial damage was likely already present in our study population, in the context of severe MR and LV dysfunction. The lack of further deterioration of LV function could therefore be considered as a therapeutic goal, even in absence of significant improvement.

4.1. RV dysfunction and outcome

RV outcome after MitraClip procedure is not yet clearly defined [21,22]. RV dysfunction (mainly due to impairment of the longitudinal shortening of the ventricular fibers) is the result of a complex interaction between the remodeled and enlarged left ventricle and atrial, septal performance, and sPAP in presence of significant MR [4]. Different studies in this context have reported conflicting results. RV dysfunction has been reported to be a strong predictor of poor cardiovascular and overall survival in patients with heart failure [10,17,39,38,40]. Conversely, isolated tricuspid regurgitation has been associated with a poor prognosis, independent of age, biventricular systolic function, RV size, and dilatation of the inferior vena cava [41]. Ghio et al. observed that RV function may be preserved despite elevated sPAP and that RV dysfunction may be observed even in patients with normal sPAP [8]. On the other hand, other studies have established an inverse relation between RV systolic function and pulmonary arterial pressure [42]. A recent observation indicates that RV dysfunction, but not significant TR, is independently associated with late survival after left heart valve surgical procedure [43]. In fact, recurrence or new development of significant tricuspid regurgitation late after left heart valve surgical procedure is frequently found and varies between 9% and 49% [44–46]. It can be speculated that in patients with severe right heart dysfunction, the higher mean trans-mitral pressure gradient determined by MitraClip acting as a “iatrogenic” mild mitral stenosis, may prevent progressive dilation of LV, but it could further overload an already malfunctioning right ventricle [47]. In our series of patients, the presence of RV dysfunction did not affect clinical outcome in terms of composite efficacy endpoint rate, which was not significantly higher compared to patient without RV dysfunction (63% vs. 47%, p = 0.567, Fig. 4). In fact, RV dysfunction improved while TR grade remained unchanged. On the other hand, the Cox proportional-hazard analysis identified advanced congestive HF and Logistic EuroSCORE >25 as the only significant independent predictors of composite efficacy endpoint. Pre-existing RV dysfunction before mitral

| Table 6 Predictors of composite efficacy endpoint (Cox proportional-hazard analysis). |
|---------------------------------|-----------|-----------|-------------|-----------|-----------|
| Univariate analysis (p value) | Multivariate analysis (p value) | HR (95% CI) |
| RVdysf | 0.416 | 0.602 | 0.76 (0.2–2.1) |
| Chronic renal failure (CRF) | 0.795 | 0.287 | 1.79 (0.6–5.2) |
| Logistic EuroSCORE >25 | 0.009 | 0.030 | 3.82 (1.1–12.8) |
| Advanced congestive HF | 0.000 | 0.001 | 6.67 (2.3–20) |
| Acute procedural success (APS) | 0.159 | 0.385 | 0.02 (0.1–2.6) |

Bold numbers indicate significance at p value < 0.05.
valve repair has been associated to further deterioration during follow up. On this basis, surgical repair before the occurrence of biventricular impairment has been advocated. The most plausible explanations of our results may be related, first, to the follow-up analysis focused on patients with successful MitraClip procedure, second, to the mild baseline RV dysfunction (TAPSE 15.5 mm, S'TDI 7.3 cm/s) of the RVdysf group. Finally, we should also take into account that mitral surgery may generate more myocardial damage than a MitraClip procedure. However, the effects of open heart surgery and extracorporeal circulation by themselves could well play a crucial role on an already diseased RV, which is known to be more vulnerable as compared to the left heart [48]. Recently, Orban et al. [49], reported a significantly higher rate of mortality in a subgroup of patient with severe biventricular heart failure and high-risk profile (mean LVEF 19.8%, TAPSE 13 mm, Logistic EuroSCORE 31.1) and found RV dysfunction and pulmonary hypertension as predictors of poor outcome (1-year mortality of 77%). Additional explanations for this difference compared to our results could be related to a different patient selection (higher LVEF and smaller LVEDD in our patients) and definition of procedural success.

The major limits of the present study are related to its observational nature, relatively small sample size and lack of a reference standard for RV functional evaluation (such as magnetic resonance imaging or three-dimensional echocardiography). Moreover, it reflects the initial experience of our center and thus the results must be regarded as hypothesis generating and exploratory and require validation in further larger studies.

4.2. Conclusions

This observational study shows that successful MitraClip implantation in patients with FMR and RV dysfunction yields significant improvement of RV function at mid-term follow-up. The presence of RV dysfunction does not appear to be a predictor of unfavorable clinical outcome in these patients. The minimally invasive approach of MitraClip could have played a significant role in avoiding the late deterioration of RV function and occurrence of tricuspid regurgitation, frequently observed after surgical mitral valve repair.

Disclosures

None.
