AdS/QCD correspondence predicts the structure of quark-antiquark potential in the static limit. We use this piece of information together with the Salpeter equation (Schrodinger equation with relativistic kinematics) and a short range hyperfine splitting potential to determine quark masses and the quark potential parameters from the meson spectrum. The agreement between theory and experimental data is satisfactory provided one considers only mesons comprising at least one heavy quark. We use the same potential (in the one-gluon-exchange approximation) and these data to estimate constituent diquark masses. Using these results as an input we compute tetraquark masses using a diquark-antidiquark model. The masses of the states $X(3872)$ or $Y(3940)$ are predicted rather accurately. We also compute tetraquark masses with open charm and strangeness. Our result is that tetraquark candidates such as $D_s(2317), D_s(2457)$ or $X(2632)$ can hardly be interpreted as diquark-antidiquark states within the present approach.

I. INTRODUCTION

Hadron spectroscopy has received in the last few years a renewed attention, both experimental and theoretical. On the experimental side several new charmonium and charmed states have been observed (for reviews see e.g. [1, 2]). The interpretation of the new states has triggered a considerable amount of theoretical work, especially so because some of the new states cannot be interpreted as ordinary quark–antiquark mesons (for reviews see [3, 4]). For some of the new states, such as the X (3872) or Y (3940) [5, 6, 7, 8, 9, 10, 11] an interpretation in terms of exotic (diquark–antidiquark bound states) has been given [12, 13, 14, 15], using a refined version of the constituent quark model [16]. On the other hand, also some conventional interpretations have been proposed. It is therefore useful to have an independent approach to the calculation of tetraquark masses in order to assess the validity of the diquark–antidiquark interpretation of the new states. This is one of the aims of the present paper. We approach this problem using a semi-relativistic method based on the use of a relativistic wave equation, the Salpeter equation. This is a Schrödinger equation with the relativistic kinematics (for previous use of this equation for hadron spectroscopy see e.g. [17] and references therein); as such, it has the usual limitations of the static potential approach, but presents the advantage of the relativistic kinematics.

A crucial point in this approach is the choice of the potential. There are several proposals in the literature, e.g. the Cornell potential [18] or its variants [19, 20]. We shall use here a modiﬁed version of a static quark potential that has been recently found in the context of the AdS/QCD correspondence [21]. As shown in [21], this potential has the same behavior expected from QCD, i.e. it is linearly rising at large distances while exhibiting a Coulomb behavior at small distances. Clearly the interpolation between these two behaviors is phenomenologically relevant if it corresponds to length scales typical of the hadrons. This is a possible way to discriminate among the different models. Another aim of this paper is therefore to nd the region where the AdS–inspired potentials di er from the usual QCD–based potentials and to see if it is of phenomenological signiﬁcance. We use the parameters of the model using, as an input, data from the meson spectrum. We then compare our results with the available experimental data for the meson spectrum and we nd a reasonable good agreement. Once the parameters of the model are ﬁxed, we can compute the diquark masses, i.e. a set of phenomenological parameters that we use, together with some additional hypothesis, to predict other spectra.

The results of the paper are as follows. Assuming a diquark–antidiquark structure of tetraquark states, we end masses for some of the X and Y states in reasonable agreement with experiment. The same procedure can be applied to tetraquarks comprising one charm quark and hidden strangeness. In this case the results are hardly compatible with the masses of possible tetraquark candidates, i.e. the states $D_s(2317)$ [22], $D_{s1}(2457)$ [23] and $X(2632)$ [23].

The paper is organized as follows. In section II we describe the model, introducing the Salpeter equation, the potential term and the numerical method adopted to solve the wave equation. In section III we determine the parameters of our model using meson spectra; the results allow a comparison with the presently available meson data. In section IV the constituent diquark masses are calculated, in the one-gluon exchange approximation. In section V we compute the spectra of a few tetraquark states. Finally, in section VI we draw our conclusions.
II. WAVE EQUATION AND THE CENTRAL POTENTIAL

The wave equation we will use in this paper is an eigenvalue equation for the hamiltonian of two point-like particles, taking into account the relativistic kinematics. It is known in the literature as Salpeter equation. In QCD it arises from the Bethe-Salpeter equation replacing the interaction with an instantaneous local potential $V(r)$ and considering a limited Fock space containing $qar{q}$ pairs only. We write the Salpeter equation for a meson consisting of a quark and an antiquark in the meson rest frame as follows ($\hbar = c = 1$):

$$q \frac{m_1^2}{r^2} + \frac{q}{r^2} + V(r) \quad (r) = M \quad (r):$$  \hspace{1cm} (1)

For central potential one can search for energy eigenfunctions with definite angular momentum, thus writing

$$\langle r \rangle = Y_{m}(\theta), \langle r \rangle:$$  \hspace{1cm} (2)

The radial wavefunction $\langle r \rangle$ satisfies the equation

$$2 Z_{-1}^{1} + \frac{r_{0}^{2}}{d r^{2}} \frac{d^{2}}{d r^{2}} + \frac{r_{0}^{2}}{d r^{2}} \frac{d}{d r} + k^{2} + \frac{m_{1}^{2}}{r^{2}} + \frac{q^{2}}{r^{2}} j_{1}(kr) j_{1}(k r^0), \langle r \rangle = [M \quad V(r)], \langle r \rangle:$$  \hspace{1cm} (3)

where $j_{0}(x)$ are spherical Bessel functions. For $r = 0$, $j_{0}(x) = \sin x$, and the Salpeter equation reduces to

$$2 Z_{0}^{1} + \frac{dr^{2}}{d r^{2}} + \frac{d}{d r} + k^{2} + \frac{m_{1}^{2}}{r^{2}} + \frac{q^{2}}{r^{2}} \sin(k r) \sin(k r^0) u_{0}(r^0) = [M \quad V(r)] u_{0}(r);$$  \hspace{1cm} (4)

where

$$u_{0}(r) = r_{0}(r):$$  \hspace{1cm} (5)

Let us discuss the potential energy. The potential $V(r)$ we adopt comprises two parts:

$$V(r) = V_{A,dS}(r) + V_{spin}(r);$$  \hspace{1cm} (6)

$V_{A,dS}(r)$ describes the central term of the potential, i.e., it contains its linearly connecting part at large distances and the short distance behavior predicted by perturbative QCD. For $V_{A,dS}(r)$ we use a slightly modified version of the potential obtained by Andreev and Zakharov [21] in the framework of the gauge/string duality approach [24,25]. $V_{spin}(r)$ is the hyperfine term to be discussed below.

A. Static quark potential

In the gauge/string duality approach [24,25] the expectation value of the Wilson loop is given by

$$\langle h W(C) \rangle = e^{S};$$  \hspace{1cm} (7)

where $S$ is an area of a string worldsheet bounded by a curve $C$ at the boundary of the AdS space (for references to the original papers see also [28]). To compute the potential the authors start with the Nambu-Goto action

$$S = \frac{1}{2} \int_{S}^{Z} d^{2} p \frac{1}{\det G_{nm} \otimes X^{n} \otimes X^{m}}:$$  \hspace{1cm} (8)

with the following background metric in $D = 5$

$$ds^{2} = G_{nm} dX^{n} dX^{m} = R^{2} \frac{h}{z^{2}} dx^{i} dx^{i} + dz^{2}; \quad h = \exp \frac{c z^{2}}{2};$$  \hspace{1cm} (9)
where $i = 0; \ldots; 3$. Choosing in (3) $1 = t$ and $2 = x$, Eq. (3) becomes

$$S = \frac{g}{2T} \int_{\frac{1}{2}}^{\frac{1}{2}} dx \frac{h}{z^2} \left( 1 + \frac{dz}{dx} \right)^2;$$

(10)

where $g = \frac{R^2}{2}$. From this action one can obtain an equation of motion for the variable $z$, from which an expression for the interquark distance $r$ is derived as follows [21]:

$$r(\ ) = 2 \int_{c_0}^{Z_{n_1}} dv \left[ \left( \frac{v}{c} \right)^2 - 1 \right] v^4 \exp \left( \frac{1}{v^2} \right) \left( 1 - 1 \right);$$

(11)

This expression depends on the constant $c$; $c$ is a parameter in the range $0; 21$. In terms of the original parameters it is given by $c = c_0^2$, with $z_0$ the value of the $n$th coordinate $z$ in $x = 0$.

The potential is obtained by computing the energy of the configuration; $r(\ )$ changes the integration variable from $x$ to $z$ in (11); the resulting integral is divergent at $z = 0$ and has to be regularized. The finite part gives

$$E(\ ) = \frac{g}{2} \int_{c_0}^{Z_{n_1}} dv \left[ \left( \frac{v}{c} \right)^2 - 1 \right] v^4 \exp \left( \frac{1}{v^2} \right) \left( 1 - 1 \right);$$

(12)

This is the potential given in [21]. The dependence $E(\ )$ is obtained by elimination of the parameter between (11) and (12); $E(\ )$ depends on two parameters $g$ and $c$.

Our potential $V_{\text{AdS}}(\ )$ is given as follows:

$$V_{\text{AdS}}(\ ) =
\begin{cases} 
E(\ ) + V_0 & r > r_m \\
E(r_m) + V_0 & r \leq r_m
\end{cases}$$

(13)

This phenomenological procedure, which has allowed to get an expression for the QCD potential with the expected properties, is known as the bottom-up approach of AdS/QCD correspondence. According to it, starting from QCD, one constructs its dual theory in such a way to reproduce some properties of QCD. Besides the QCD potential, many results have been obtained so far, such as the determination of the numerical values of some observables [27], in good agreement with experimental data, or the linearity of the Regge trajectories [22,23].

The expression (12) derives from the metric (9); we have also tried to use a slight modification of the dilaton term in (9), specifically, changing the power of $z$ at the exponent. We found that, for any power of $z$, the potential has the same behavior, i.e., Coulomb-like for small $r$ and linearly rising for large $r$. As far as the QCD potential is concerned they are the most plausiblecandidate for the AdS metric of the QCD dual space.

We have introduced a constant term $V_0$ in the potential. This is allowed because the more general string action is obtained by adding to the Nambu-Goto action a term

$$S = C_R \int \sqrt{\det G_{nm}} \theta^X \theta^X;$$

(14)

where $R$ is the scalar curvature. One can easily prove that adding $S$ to $S$ corresponds to add a constant term to the interquark potential.

Another modification appearing in (13) is the introduction of a cut-off at short distances $r < r_m$ [17]. The reason lies in the use of the relativistic kinematics embodied in Eq. (1). As a matter of fact, the
potential $E(\ )$ in (12) diverges as $r \to 0$. It is a Coulombic divergence occurring at $r = 0$, because the small distance region corresponds to $r \to 0$. This divergence is harmless if one uses the Schrodinger equation for the wavefunction, but in the case of the Salpeter equation (1) it produces an unphysical logarithmic divergence for the s-wave wavefunction for $r \to 0$. To cure this unphysical singularity arising from the static approximation one assumes a constant potential for $r$ smaller than

$$r_m = \frac{1}{M} : \quad (15)$$

The proportionality constant can be fixed using quark duality arguments [30], which shows that one expects different results for the equal and unequal mass cases. Thus we use

$$r_m = \frac{k}{M} \quad (m_1 = m_2) ;$$

$$r_m = \frac{k^2}{M} \quad (m_1 \neq m_2) : \quad (16)$$

This concludes the discussion of the central part of the potential.

### B. Spin term

Let us now discuss the spin term. In the approximation of one-gluon exchange one knows that the spin term is enhanced at short distances and is proportional to inverse quark masses. Following [31] we use

$$V_{\text{spin}}(r) = A \frac{r(r)}{m_1 m_2} S_1 \quad (17)$$

where $\sim$ is a function enhanced at small distances. In the constituent quark model the constant $A$ is proportional to $\alpha_s$, which is a running coupling constant, so we have introduced two different parameters for mesons containing at least one charm and one bottom quark ($A_c$ and $A_b$, respectively). We adopt the smeared delta function used in ref. [31]:

$$\sim(r) = \frac{3}{4 \pi} e^{-2r^2} : \quad (18)$$

The potential depends therefore on 8 parameters: $c; g; V_0; k; k^2; A_c; A_b;$. Moreover, we have to fix the constituent quark masses: $m_u = m_d \quad m_s, m_c, m_b$.

### C. Numerical solutions

To solve Eq. (1) we use the Multihopp method [32], which, as shown in [17], is particularly useful for equations of the form considered here. By this method one transforms the integral equation in a set of linear equations introducing $N$ parameters $k_i$ called Multihopp’s angles. The set of equations is as follows (we refer the reader to [13] for further details):

$$B_{km}(k) = M_{km}(m) \quad (19)$$
where \( (k) = u_0(\cot_k) \), \( k = \frac{N}{N+1} \) (\( k = 1; \ldots; N \)) and

\[
B_{km} = \frac{2}{N+1} \sum_{j=1}^{N} \sin(jm)I_{jk} \tag{20}
\]

with

\[
I_{jk} = \frac{2}{Z} \lim_{n \to 0} \frac{d}{dx}(\sin^{2}(\cot x^{2}k^{2}) + \frac{1}{(\cot x^{2}k^{2})^{2}}) + \frac{1}{(\cot x^{2}k^{2})^{2}} - 2\cot jx \sin 2\cot jx \] \tag{21}

Notice that the writing in Eq. (21) makes explicit the prescription to avoid the divergence in the integral both for the massive and the massless case; \( K_{1}(x) \) is a modified Bessel function.

III. MESON SPECTRUM

The strategy we follow to evaluate the parameters of the model is to extract them by using information from the mesonic spectrum. Subsequently, in the next sections we use this information to deduce quark masses and, from these data, diquark and tetraquark masses. In principle one might follow a different strategy, using all available experimental data to get a best set of the parameters. We have not followed this approach because to get the spectrum of diquarks and tetraquarks we make further assumptions, e.g. the use of the quark-quark potential as obtained by one-gluon-exchange approximation.

Therefore, after having fixed the parameters from the mesonic spectrum, we will use below experimental data for \( X \) and \( Y \) states to test the hypothesis of diquark-antidiquark structure of these exotics.

In order to get the numerical values for the parameters \((c; g; V_{0}; k; k'; A_{c}; A_{b}; m_{u} = m_{d}; m_{s}, m_{c}, m_{b})\) we use the Salpeter equation for mesons with both \( J^{P} = 0^{+} \) and \( 1^{+} \). We consider only mesons containing at least one heavy \((c; b)\) quark, because we expect that the approximation of static potential works better for these states. The set of available data comprises about 20 masses. The results of the best fit are reported in Table I for heavy mesons. They correspond to the following set of parameters:

\[
c = 0.3 \text{ GeV}^{2}; \quad g = 2.75; \quad V_{0} = 0.49 \text{ GeV} \quad \text{A}_{c} = 7.92 \text{ GeV}^{3}; \quad \text{A}_{b} = 3.09 \text{ GeV}^{3} \quad k = 1.48; \quad k' = 2.15; \quad \text{m}_{c} = 1.73 \text{ GeV}; \quad \text{m}_{b} = 5.139 \text{ GeV}; \quad \text{m}_{u} = \text{m}_{d} = \text{m}_{s}; \quad \text{m}_{c} = 0.302 \text{ GeV}; \quad \text{m}_{s} = 0.454 \text{ GeV}; \quad \text{m}_{c} = 1.733 \text{ GeV} \tag{22}
\]

In order to test the limits of the model we also compute the masses of states containing only light \((u; d; s)\) quarks. The results for their spin averaged masses are shown in Table I. For the lightest mesons we do not allow large deviations, while such a discrepancy is somewhat reduced in case of \( ss \) and for higher radial excitations. This is reasonable, since a constituent quark model with instantaneous interaction is not able to describe the chiral dynamics of light states. The better accuracy of the \( ss \) system allows us to fix the spin constant \( A_{s} \) (in Eq. 17) from this channel, obtaining \( A_{s} = 11.3 \text{ GeV}^{3} \), which will be used in the calculation of the masses of the lightest diquarks. With this value, we obtain for \( a_{0} \) a mass \( m_{0} = 1.011 \text{ GeV} \) (the experimental value is 1.019 GeV) and for \( a_{0}^{'} \) a mass \( m_{1} = 1.663 \text{ GeV} \) (the experimental value is 1.680 GeV).

It might be useful at this stage to study the effect of the relativistic kinematics on the equation of state. To this end we have used the same potential, with the values of parameters indicated by Eq. (22), with two

different equations: the Salpeter equation [1] and the Schrodinger equation. The results of the two equations for mesons with \( J^P = 1 \) are reported in Table III. The comparison between the two computed spectra and the experimental one shows that, as expected, the results obtained by the Salpeter equation are more accurate than the ones obtained by the Schrodinger equation. We conclude that the advantage of using the Salpeter equation is particularly significant for the charmed states, since this equation takes into account a relevant source of corrections, i.e. those due to the relativistic kinematics.

A final comment is for the use of the AdS/QCD inspired potential. As we stressed in the introduction, many potentials have been used in the literature to study meson spectra. If they have to reproduce the constraints

of QCD they must rise linearly at large distances and have a Coulomb-like behavior at small $r$. We wish to compare the potential we have used, i.e., $V_{AdS} = E(r) + V_0$ in Eq. (13), with a typical QCD-inspired potential, i.e., the Richardson’s potential:

$$V_R(r) = \frac{8}{33} \frac{2n_f}{r} f(r) + V_1;$$  \hspace{1cm} (23)

where $n_f$ is a parameter, $n_f = 3$ is the number of flavors and

$$f(t) = \frac{4}{Z} \int_0^1 dq \frac{\sin(qt)}{q} \left( \frac{1}{\ln(1 + q^2)} \right) \frac{1}{q^2};$$ \hspace{1cm} (24)

To allow for a comparison, similarly to what we have done for the AdS potential we have added a constant term $V_1$ to the original Richardson’s potential. We choose the value of $V_1$ imposing that the linearly
conning parts of $V_{A,DS}$ and $V_A$ coincide at large $r$. For $V_{A,DS}$ we use the values obtained by the meson spectrum; this gives for $V_1$ the values $= 0.44$ GeV and $V_1 = 0.6$ GeV.

We are now able to compare the two potentials and the result is in Fig. 4. It shows that, even though the two potentials almost coincide asymptotically, they differ significantly in the intermediate region, which is the region of interest from a phenomenological point of view.

IV. DIQUARK MASSES

In view of the applications to be discussed in the subsequent sections we wish to derive a set of parameters that we call active diquark masses or simply diquark masses.

In the one-gluon exchange approximation the color antisymmetric channel corresponding to antitriplet in the decou position

$$3 \times 3 = 3 \times 6$$

is attractive. Moreover, in the same approximation the attractive potential between the two quarks $QQ$ is half the one between a quark $Q$ and an antiquark $Q$. We therefore adopt, as usual, the following value for the potential between the two quarks comprising the diquark:

$$V_{QQ} = \frac{1}{2} V_{Q}$$

However it must be kept in mind that this approximation holds only for the QCD perturbative interaction and might be modified in the linearly conning part. Therefore we expect it works better for heavy diquarks, as, in this case, the interaction explores smaller distances than for light diquarks.

To derive the diquark effective masses we use the Salpeter equation with the same set of parameters used to obtain the meson spectrum. Also in this case, as for mesons, one has that the spin term works differently for $S = 1$ and $S = 0$ states. It adds a positive contribution for $S = 1$ and subtracts the same contribution multiplied by a factor of $\frac{3}{2}$ for $S = 0$.

Table IV: Diquark masses. The masses of the present paper are obtained by the Salpeter equation (see text). The model in \cite{34,35} uses a quasipotential of the Schrodinger type \cite{34} for $QQ$ (resp. $QQ$) means a spin 1 (resp. $S = 0$) diquark $QQ$. Units are GeV.

| State $QQ$ | Mass (this paper) | $\text{[34,35]}$ | $QQ$ | $\text{[34,35]}$ | $QQ$ | $\text{[34,35]}$ |
|------------|-------------------|----------------|------|----------------|------|----------------|
| $f_{qg}$   | 0.980             | 1.069          | $|q\rangle$ | 0.979         | 0.948 |
| $f_{sg}$   | 1.096             | 1.203          | $|s\rangle$ | 2.120         | 1.973 |
| $f_{c\bar{q}}$ | 2.168        | 2.036          | $|c\rangle$ | 2.235         | 2.091 |
| $f_{c\bar{g}}$ | 2.276        | 2.158          | $|c\rangle$ | 2.235         | 2.091 |
| $f_{c\bar{c}}$ | 3.414        | 3.226          | $|c\rangle$ | 2.235         | 2.091 |
| $f_{b\bar{q}}$ | 5.526        | 5.381          | $|b\rangle$ | 5.513         | 5.359 |
| $f_{b\bar{g}}$ | 5.630        | 5.482          | $|b\rangle$ | 5.619         | 5.462 |
| $f_{b\bar{c}}$ | 6.741        | 6.536          | $|b\rangle$ | 6.735         | 6.519 |
| $f_{b\bar{b}}$ | 10.018       | 9.778          | $|b\rangle$ | 6.735         | 6.519 |

The results are reported in Table IV; diquarks with $S = 0$ are denoted as $[QQ]$, those with $S = 1$ as $fQQg$. We have also reported the results of a different model by the authors of Refs. \cite{34,35} who use a...
quasipotential of the Schrodinger type \[34\]. We also note that in a series of papers \[12,13,14,15\] Maiani and collaborators have put forward an interpretation of the new X and Y states, as well as of light scalars such as \(\phi(980)\), \(\rho(770)\), \(f_0(980)\), etc., as four-quark states comprising a diquark and an antidiquark (see below). They use a quark constituent model similar to the well known De Rujula-Glashow model \[16\]. A lo in \[12,13,14,15\] an effective diquark mass is used, however its meaning is different from ours, because the constituent quark mass used in these papers takes into account both the average kinetic energy and the potential energy, differently from our case, where a wave equation is considered. Therefore no numerical comparison is possible among our values for diquark masses and those found in \[12,13,14,15\].

V. TETRAQUARK SPECTRUM

In this section we wish to discuss the possibility that two diquarks, more precisely a diquark and an antidiquark, combine to produce a tetraquark state. Such an interpretation was advanced long ago in order to give an interpretation of light scalars \(\phi(980)\) and \(f_0(980)\) in terms of constituent quarks \[3\]. The recent discovery of new states, with both hidden and open charm, has raised a new interest for this model, although the interpretation of the new states is controversial, see for reviews \[3\] and \[4\].

Let us start with the state \(X(3872)\) \[3,5,6,7,8,9,10\]. The average mass of this state is 3870 \(\pm 4\) MeV and its quantum numbers should be \(J^P = 1^+\). The assignment \(C = +1\) follows from the fact that the decay \(X \rightarrow J/\psi K^+\) is observed. Moreover the decay \(X \rightarrow \psi K^+\) is also observed, the part of the 2 invariant mass spectrum that can be ascribed to a \(J^P = 1^+\) decay is consistent with a wave decay of the \(X\) state. From this the assignment \(J = 1\) follows. Finally the angular distribution in this channel is compatible with \(J = 0\) and therefore the only remaining possibility is \(J = 1\) or \(J = 2\). If the peak in the \(B^+ \rightarrow D^0 (\phi(1020)) \rightarrow D^0 \pi^+\) decay channel at 3875.4 MeV (at \(2\) from the mass of \(X(3872)\)) is interpreted as due to this state, then the \(J = 2\) should be excluded, which leaves us with \(J = 1\) only.

Several interpretations have been proposed for this state. Since the mass of this state almost coincides with the sum of the masses of the \(D^0\) and \(\bar{D}^0\) states, a natural explanation is that of a molecular state comprising the two charm mesons \[36,37,38,39,40,41,42,43\]. The interpretation as a \(0^+_c\) state \[44\] is unlikely because of the small value of the ratio \(B(X \rightarrow J/\psi K^+) / B(X \rightarrow \psi K^+)\) and for the value of the mass. Also the interpretation as a \(J^P = 1^+\) diquark-antidiquark state is difficult due to the fact that lattice data predict larger masses for states of this kind and for a comprehensive list of other models see \[3\].

As mentioned above, another possibility is that this state comprises four quarks. They might be a four quark cluster without internal structure \[45\] or a bound state of two diquarks, as first discussed in \[13\] and more recently in \[30\]. We shall return to this interpretation below.

The Belle collaboration observes two bumps, at 3940 MeV. They do not necessarily correspond to two different states. The state called \(Y(3940)\) is observed in the decay \(\psi(2S) \rightarrow B^+ \rightarrow \psi K^+\). Its reported mass is \(M = 3942 \pm 11\) MeV. Its interpretation as a charmonium \(\Sigma\) state is possible, but should be corroborated by the observation of the decay \(B \rightarrow \psi K^+\), which has not yet been seen. Also the interpretation as a \(J^P = 1^+\) \(c\bar{c}\) diquark is difficult due to the fact that lattice QCD computations \[47,48\], is significantly larger than the measured value. An in this case a four quark interpretation is possible, in particular the state might be the \(2^\pm\) state predicted by the diquark-antidiquark scheme \[11\]. The other state \(X(3940)\) needs confirmation; it is observed \[49\] in double charm production: \(e^+ e^- \rightarrow X \rightarrow DD\). Its possible interpretations are the states \(0^+_c\) or \(0^-_{cc}\).

We wish to test the interpretation of these states as diquark-antidiquark bound states, in the same spirit...
of Refs. 12, 13, 14, 15 and 34. Note however that our approach is different from that followed in these papers. As a matter of fact we apply a wave equation for the tetraquark states, comprising the diquarks \((Q_1Q_2)\) and \((Q_3Q_4)\), as follows

\[
q \left( m_{12}^{-2} \right) r^2 + q \left( m_{34}^{-2} \right) r^2 + V(R) + \ell(R) = M \ell(R).
\]

Here \(M \ell\) and \(\ell(R)\) are the tetraquark mass and wavefunction respectively, \(m_{ij}\) is the effective diquark mass computed above; \(R\) is the distance between the centers of the two diquarks. We take into account the structure of the diquarks by defining a smeared potential as follows:

\[
V(R) = \frac{1}{N} \int dr_1 \int dr_2 \int (r_1) \int (r_2) V(r_1 + r_2)
\]

with

\[
N = \int dr_1 \int dr_2 \int (r_1) \int (r_2) \int.
\]

In these equations \(\ell(R)\) is the wave function of the diquark whose content is \(Q_1Q_2\) (resp. \(Q_3Q_4\)); for \(V(r)\) we use \([3]\), and the masses appearing in the spin term of Eq. (17) are diquark masses. In this paper we only consider diquark with internal orbital quantum number \(\ell' = 0\); therefore \(\ell(R)\) is related to \(u_0(r)\) defined above as follows:

\[
\ell(R) = \frac{u_0(r)}{r}.
\]

In Fig. 2: The squared diquark wavefunction (in GeV\(^{-1}\)) versus \(r\) (in GeV\(^{-1}\)). Data correspond to the diquark [eq.]

Since \(\ell(R)\) is strongly peaked at \(r = 0\) (see Fig. 2) we cut-off the integrals in Eqns. (28) and (29) at \(R_0\) where \(R_0\) is the peak value of \(u_0(r)\), the wavefunction of the tetraquark. This procedure ensures that the two diquarks are on average inside the tetraquark’s bag. In Fig. 3 is represented \(u_0(r)\) for the tetraquark [eq.]

We finally note that we use for \(\ell(R)\) the result obtained from the diquark wave equation. This is only approximately correct because that equation provides the diquark wavefunction in the diquark rest frame, whereas (27) holds in the tetraquark rest frame. However for diquarks comprising heavy quarks (c; b) the average diquark velocity is small (we estimate \(0.15\) for diquarks with open charm and \(0.06\) for diquarks with open bottom). Therefore we can neglect the distortion induced by the Lorentz boost on the wavefunction. The effect of convoluting the potential with the wavefunctions in (28) is shown in Fig. 4.

In Tables V and VI we present our predictions for the four-quark states with hidden charm and hidden bottom respectively. Notice that we have adopted the same values of the free parameters used in the
FIG. 3: The tetraquark wavefunction $u_0(r)$ (in GeV$^{-1/2}$) versus $r$ (in GeV$^{-1}$). Data correspond to the tetraquark $[cq]cqcg$.

FIG. 4: The potential between static diquarks (dashed line) and its modification according Eq. (28) (solid line). Units are GeV (V) and GeV$^{-1}$ (r). Data refer to the $[cq]cqcg$ potential.

previous sections, so basically our calculation is parameter-free. It is remarkable that in the two cases when a comparison with experiment is possible, our results agree, within the errors, with the data. A further comment is the following. A peculiar feature of the diquark-antidiquark scheme for the $X$ state is the prediction of four different states with mass differences of a few MeV. Two of them are neutral: $X_u = [cu][cu], X_d = [cd][cd], $ and two charged: $X^+ = [cu][cd], X^- = [cd][cu].$ It is possible that the two states seen through the decay modes $J = 1^+$ and $D^0\bar{D}^0$ are really different and they would correspond to the neutral states $X_u, X_d$ since the mass difference between the two bumps at 3871 and 3876 MeV is of the same order of magnitude of the mass difference between the $u$ and $d$ quarks. According to [15] this is a piece of evidence in favor of the four quark interpretation of these states. We have not included any mass difference between $u$ and $d$ quarks, but also in our scheme one would expect a mass difference of a few MeV between the two neutral states. We note that in [15] a strategy to find the two missing charged partners is delineated. We refer to this paper for further details.

By our model we can compute also radial excitations of tetraquarks. For example the first radial excitations of the two $X$ states with $1^+$ have mass $m = 4.421$ GeV and $m = 4.418$ GeV respectively. In Ref. [50] the
TABLE V: Four-quark states with hidden charm interpreted as bound states comprising a diquark (cq) and an antidiquark (cp). fQQ g (resp. fQQ ) means a spin 1 (resp. spin 0) diquark QQ. The masses of the present paper are obtained by the Salpeter equation (see text). The model in [24-25] uses a quasi potential of the Schrödinger type [26]. Ref. [13] uses a constituent quark model (’m means that the experimental value is used as an input in this case). Units are GeV.

The state Z (4433), recently observed by the Belle Collaboration [51] through the decay Z (4433) → (2S), is interpreted as the first radial excitation of one of these states. Although the difference between theory and experiment in this case is larger than, say, for X (3872) or Y (3940), this interpretation is compatible with our results because of the theoretical errors of the present model. A new exotic state is Y (4260), found by the BaBar Collaboration [52] and confirmed by CLEO [53] and BELLE [54]. It is interpreted in [14] as an orbital excitation of a tetraquark state, an interpretation we are neither able to confirm nor to disprove, as we have limited the analysis to the ‘= 0 states.

Let us now comment on the light tetraquarks. We do not include them in the Tables because for them our results are less reliable; moreover, as discussed in connections with Eqs. [28], [29], the distortion of the diquark wavefunction due to the relativistic motion is larger for light diquarks, and its neglect generates a greater error.

Let us finally comment on the possible existence of tetraquarks comprising a heavy diquark and a light diquark. We present in Table VII our predictions for tetraquarks with open charm and strangeness and compare them with the prediction of the constituent quark model of Ref. [13]. In [13] the state 0^- is associated with the particle D_s (2317) [24], 1^- with D_s (2457) [24] and 2^- with X (2632) [23]. Our results
TABLE VII: Comparison between the results of the present model and those of Ref. [13] for tetraquarks with open charm and strangeness. Units are GeV.

| J^P | Flavor content | Th. mass (this paper) | Th. mass (model [13]) |
|-----|----------------|----------------------|-----------------------|
| 0^+ | [cq][qgs]      | 2.840                | 2.371                 |
| 0^+ | fcqfg[gs]      | 2.503                | 2.424                 |
| 1^+ | fcq[qgs]       | 2.880                | 2.410                 |
| 1^+ | fcqfgqg        | 2.748                | 2.462                 |
| 1^+ | [cq][qlg]      | 2.841                | 2.571                 |
| 2^+ | fcqfgqg        | 2.983                | 2.648                 |

are signiﬁcantly different from those of [13]. Again, this might be due to the limitations of one or both the constituent quark models. In any event, on the basis of the results in Section III, we do not expect theoretical errors larger than a few hundred MeV for the results of the present model in Table VII, so that we do not support the interpretation of the states D_s(2317), D_s(2457) and X(2632) as tetraquark charm ed states with open strangeness. In [55] these states are interpreted as a mixture of P-wave quark-antiquark states and four-quark components.

VI. CONCLUSIONS

We have developed an application and, at the same time, a test for the QCD potential found by means of the AdS/QCD correspondence. We have put it in a semi-relativistic wave equation and tested meson spectra. Our result is that this model, with the AdS/QCD potential plus a contribution from spin interaction, can reproduce the experimental data except for the lighter states (KK). This agreement has motivated us to make some predictions on the masses of tetraquarks, considering them as bound states of a diquark and an antiquark. Our conclusions are that some tetraquark states with appropriate flavor content can be identified with the particles X(3872) and Y(3940). On the other hand, the present model does not favor the interpretation of some charmed positive parity particles with strangeness as tetraquark states.
