ABSTRACT

Recently, the GeV radiation during the X-ray flare activity in GRB 100728A was detected by Fermi/LAT. Here, we study the dynamics and emission properties of a collision between two homogeneous shells based on the late internal shock model. The GeV photons can be produced from X-ray flare photons being upscattered by relativistic electrons that are accelerated by forward–reverse shocks, where the involved radiative processes include synchrotron self-Compton and crossing inverse-Compton scattering. Using analytical and numerical calculations, the observed spectral properties in GRB 100728A can be well explained.

Key words: gamma-ray burst: general – radiation mechanisms: non-thermal

1. INTRODUCTION

Gamma-ray bursts (GRBs) are the brightest explosive phenomena in the universe, the study of which has been one of the most interesting fields in astrophysics. Since its launch in 2008, the Large Area Telescope (LAT) on board the Fermi satellite has detected high-energy photons in the energy range from 20 MeV to 300 GeV. Several mechanisms have been proposed to predict the origin of GeV photons along with the GRB afterglow phase (for a review, see Zhang2007). (1) In the external shock scenario, high-energy photons may be produced by synchrotron radiation and synchrotron self-Compton (SSC) processes from forward–reverse shocks (Meszaros et al. 1994; Meszaros & Rees 1994; Dermer et al. 2000; Zhang & Meszaros 2001; Sari & Esin 2001) or crossing inverse-Compton (CIC) processes between forward–reverse shocks (Wang et al. 2001a, 2001b; Pe’er & Waxman 2005). (2) In the hadronic and pion decay scenarios, there may be synchrotron radiation of protons, π+ from pγ, pn, and pp interactions, and positrons produced from π+ decay and π0 decay from pγ interactions (Gupta & Zhang 2007). (3) Electrons from pair productions during the interaction of >100 GeV photons from GRBs with cosmic infrared background photons might also emit GeV photons by inverse scattering off cosmic microwave background photons (Dai & Lu 2002; Wang et al. 2004).

On the other hand, one of the key discoveries has been bright X-ray flares superimposed on underlying afterglow emission from nearly half of the GRBs observed by Swift (Burrows et al. 2005). The rapid rise and decay behavior of X-ray flares is widely understood as being due to some long-lasting activity of the central engines. Such activity might be caused by an instable accretion disk around a black hole (Perna et al. 2006), the accretion of fragments of the collapsing stellar core onto a magnetic barrier (Proga & Zhang 2006), or magnetic reconnection of a newborn neutron star (Dai et al. 2006).

GRB 100728A is a case with simultaneous detections by Swift and Fermi (Abdo et al. 2011), which detected GeV photons during X-ray flares. The GeV photons during the X-ray flare activity detected by Fermi/LAT have been thought to arise from external inverse-Compton (EIC) scattering off X-ray flare photons by electrons in a relativistic forward shock (Fan & Piran 2006; Fan et al. 2008; Wang et al. 2006; He et al. 2012). Here, we propose a different explanation, in which the detected GeV photons are produced by SSC and CIC scattering off X-ray flare photons by electrons accelerated in the late internal shock model. This model was suggested by Fan & Wei (2005) and Zhang et al. (2006), and its motivations are based on the two following facts. First, the rapid rising and decaying timescales and their distributions of X-ray flares require that the central engine restarts at a later time (Lazzati & Perna 2007). Second, Liang et al. (2006) fitted the light curves of X-ray flares detected by Swift by assuming that the decaying phase of an X-ray flare is due to the high latitude emission from a relativistic outflow. These authors found that the ejection time of this outflow from the central engine is nearly equal to the peak time of an observed X-ray flare produced by the outflow.

This paper is organized as follows. We calculate the dynamics of a collision between two shells and the properties of synchrotron and inverse Compton (IC) emission to produce X-ray flares and higher-energy emissions in Section 2. In Section 3, we present numerical calculations and light curves of the model; in addition, we apply this model to GRB 100728A and present constraints on the model parameters. In the last section, some conclusions are given.

2. THE SYNCHROTRON AND IC EMISSION FROM LATE INTERNAL SHOCKS

In the internal shock model, a fireball consisting of a series of shells with different Lorentz factors can form prompt emission through shell–shell interactions. Similarly, collisions between shells with different velocities ejected from the central engine at late times after the GRB trigger can form late internal shocks, the emission from which reproduces X-ray flares.

2.1. Dynamics of Two Shell Collisions

For one X-ray flare, here we consider the following shell–shell collision: a prior slow shell A with bulk Lorentz factor γA and kinetic-energy luminosity Lk,A, and a posterior fast shell B with bulk Lorentz factor γB(γA < γB) and kinetic-energy luminosity Lk,B. The collision of the two shells takes place at radius

\[
R_{\text{col}} = \frac{\beta_B \Delta t}{(\beta_B - \beta_A)} \lesssim \frac{2\gamma_A^2 c^2 \Delta t}{1 - (\gamma_A/\gamma_B)^2} \equiv \frac{2\gamma_A^2 c^2 \Delta t}{1 - (\gamma_A/\gamma_B)^2},
\]
where $\Delta t_3$ is the ejection interval of the two shells and $\delta t$ is the redefined interval. During the collision, there are four regions separated by forward–reverse shocks: (1) the unshocked shell A, (2) the shocked shell A, (3) the shocked shell B, and (4) the unshocked shell B, where regions 2 and 3 are separated by a contact discontinuity.

The particle number density of a shell measured in its comoving frame can be calculated by

$$n'_i = \frac{L_{k,i}}{4\pi R^2 y'_i^2 m_p c^3},$$

where $R$ is the radius of the shell and the subscript $i$ can be taken as A or B.

Yu & Dai (2009) analyzed the dynamics of a late-time shell–shell collision in detail. In order to get a high theoretical X-ray luminosity, it is reasonable to assume $y_A \ll y_B$ and $L_{k,A} = L_{k,B} \equiv L_k$. Assume that $y_1$, $y_2$, $y_3$, and $y_4$ are the Lorentz factors of regions 1, 2, 3, and 4, respectively. As a result, we have $y_1 = y_A$, $y_4 = y_B$, and $n'_1 \gg n'_4$. If a fast shell with a low particle number density catches up with a slow shell with a high particle number density and they collide with each other, then a Newtonian forward shock (NFS) and a relativistic reverse shock (RRS) may be generated (Yu & Dai 2009). So we can obtain $y_1 \simeq y_2 = y_3 = y \ll y_4$. Then, according to the jump conditions between the two sides of a shock (Blandford & McKee 1976), the comoving internal energy densities of the two shocked regions can be calculated by $e'_2 = (y_2 - 1)(4y_2 + 1) n'_1 m_p c^2$, $e'_3 = (y_3 - 1)(4y_3 + 3) n'_1 m_p c^2$, where $y_2 = (1/2)(y_1/y_2 + y_2/y_1)$ and $y_3 = (1/2)(y_1/y_4 + y_4/y_1)$ are the Lorentz factors of region 2 relative to the unshocked shell, and region 3 relative to region 4, respectively. It is required that $e'_2 = e'_3$ because of the mechanical equilibrium. We have

$$y_1^2 - y_2^2 = \frac{y_2}{y_1} = \left(\frac{y_1}{y_4}\right)^2 \equiv f.$$ (3)

Two relative Lorentz factors can be calculated by $y_2 \approx (f y_4^2/7 y_4^2 + 1 = 8/7)$ and $y_3 \approx (y_4/2 y_2)$ $\ll y_2$. Assuming that $t$ is the observed shell interaction time since the X-ray flare onset, the radius of the system after the collision can be written as

$$R = R_{\text{col}} + 2y^2 c t \simeq 2y_3^2 c (t + \delta t).$$ (4)

During the propagation of the shocks and before the shock crossing, the total electron numbers in regions 2 and 3 can be calculated by $N_{e,2} = 8\pi R^2 n'_1(\gamma y_2^2)\beta y^2 c t$ and $N_{e,3} = 8\pi R^2 n'_1(\gamma y_3^2)\beta y^2 c t$ (Dai & Lu 2002), respectively. We can easily find that the electron number in region 2 is larger than that in region 3.

### 2.2. Synchrotron Emission from Two Shocked Regions

As usual, we assume that the fractions of $e_B$ and $e_c$ of the internal energy density in a GRB shock are converted into the energy densities of the magnetic field and electrons, respectively. Thus, using $B'_i = (8\pi e_B^2 e_i)^{1/2}$ for $i = 2$ or 3, the strength of the magnetic field is calculated using

$$B'_i = B'_3 = \left[\frac{e_B L_k}{2y^6 c^3 (t + \delta t)^2}\right]^{1/2}.$$ (5)

The electrons accelerated by the shocks are assumed to have a power-law energy distribution, $dn_{e,i}/d\gamma_{e,i} \propto \gamma_{e,i}^{-p}$ for $\gamma_{e,i} \gg 1$.

The synchrotron emission is a minimum Lorentz factor, $y_{e,m,i}$, where $y_{e,m,i}$ is the minimum Lorentz factor. According to $y_{e,m,i} = (m_p/m_e)(p - 2 - p - 1)e_i(y_{e,m}^{-1} - 1)$ (where $y_{e,m} = y_2$ or $y_{e,m} = y_3$ in region 2 or 3), the minimum Lorentz factor can be written as

$$y_{e,m,1} = 2.8 \times 10^3 g_p e_i c (\gamma_{e,m}^{-1} - 1) y_{1,1}^{-1},$$ (6)

$$y_{e,m,2} = 2.8 \times 10^3 g_p e_i c \gamma_{e,m}^{-1} y_{2,1}^{-1}$$ (7)

where $e_i = e_i/\gamma_{e,m}^{-1} y_{4,2}. y_{4,2} = \gamma_4/10^{2.5}, y_{1,1} = y_1/10^4,$ and $g_p = 3(p - 2)/2(p - 1)$.

Moreover, the cooling Lorentz factor, above which the electrons lose most of their energies, $y_{e,c,i} = 6\pi m_p c/(y_{1,1} \sigma T B'_i y i t)$, should be given by

$$y_{e,c,3} = y_{e,m,3} \approx 1.4 \times 10^3 y_{0,1}^{4} y_{3,1}^{4} t_{-2}^{1/3} (t + \delta t)^{3/2} (t + \delta t)^{3/2}.$$ (8)

where $y_i = 1 + Y_i$ is the ratio of the total luminosity to synchrotron luminosity, and $Y_i \approx (4\pi\gamma_{e,c}/\gamma_{e,m}^{-1} - 1)/2$ is the Compton parameter, which is defined by the ratio of the IC to synchrotron luminosity, with $Y_i = \min[1, (y_{e,c,i}/y_{e,m,i})^{3/2} - 1]$ (Sari & Esin 2001). Here, we assume $e_i = 0.3$ and $e_B = 0.03$ in our calculations, so $Y_i < 3$ can be easily obtained so that we can assume $y_i \sim 1$. Figure 1 presents the changes of $Y_i$ and shows that it is reasonable to assume $y_2 \sim y_3 \sim 1$. Thus, the IC luminosity is comparable with the synchrotron luminosity.

In order to obtain the synchrotron emission spectrum, we consider

$$v_{m,i} = \frac{q_e}{2\pi m_e c} B'_i y_{e,m,i}^2 y_i,$$ (9)

and

$$v_{c,i} = \frac{q_e}{2\pi m_e c} B'_i y_{e,c,i}^2 y_i.$$ (10)

where $q_e$ is the electron charge. Four characteristic frequencies in regions 2 and 3,

$$v_{m,2} \approx 4.5 \times 10^{13} e_i c^2 B'_{2} B_{0,3}^{1/2} f_{-2}^{1/2} t_{-2}^{1/2} \gamma_2^{-2/5} (t + \delta t)^{-1/2} \text{Hz},$$ (11)

$$v_{m,3} \approx 5.0 \times 10^{17} e_i c^2 B'_{3} B_{0,3}^{1/2} f_{-2}^{1/2} t_{-2}^{1/2} \gamma_3^{-2/5} (t + \delta t)^{-1/2} \text{Hz},$$ (12)

and

$$v_{c,2} \approx v_{c,3} \approx 1.3 \times 10^{17} e_i c^2 B_{0,3}^{1/2} f_{-2}^{1/2} t_{-2}^{1/2} \gamma_2^{-4} (t + \delta t)^{3/2} \text{Hz},$$ (13)

can be obtained. In Figure 2, their time evolutions are presented. From this figure, we can easily see that region 2 and region 3 are in the slow cooling regime at very early times, and subsequently region 2 is in the slow cooling regime but region 3 is in the fast cooling regime, and finally both regions are in the fast cooling regime. As a result, the spectral index between $v_{m,i}$ and $v_{c,i}$ of region 2 and region 3 evolves with time as in Sari et al. (1998). It is reasonable to think that region 3 will be in the fast cooling regime, while region 2 is in the slow cooling regime at early times and in the fast cooling regime at later times. By applying the formula

$$F_{v,\text{max},i} = \frac{N_{e,i} m_e c^2 \sigma_T}{4\pi D_i^2} B'_i y_i,$$ (14)
Figure 1. Ratio $Y_i$ of the IC to synchrotron luminosity as a function of time. The black dotted line represents the forward and reverse shock crossing time. Here, we assume that the two shocks cross the two shells at a similar time $T_{crs} = 20$ s. After the shock crossing time, the merged shell expands adiabatically if $s = 3$ is assumed. The other parameters $L_{k,1} = L_{k,4} = 10^{50}$ erg s$^{-1}$, $\gamma_1 = 10$, $\gamma_4 = 300$, $p = 2.5$, $\epsilon_e = 0.3$, $\epsilon_B = 0.03$, $\theta_{jet} = 0.1$, and $z = 1$ are taken in numerical calculations. (A color version of this figure is available in the online journal.)

Figure 2. Four characteristic frequencies as functions of time. The black vertical dotted line represents the forward and reverse shock crossing time. A similar crossing time $T_{crs} = 20$ s of two shocks is also assumed. After the shock crossing time, the merged shell expands adiabatically if $s = 3$ is assumed. $T_{m}(T_{c})$ ist he f et ih t e b reak frequency $\nu_m(\nu_c)$ passing through the X-ray band (black horizontal solid line, $10^{17}$ Hz) in region 3 (Yu & Dai 2009). The same parameters as in Figure 1 are taken in numerical calculations. (A color version of this figure is available in the online journal.)

where $D_L$ is the luminosity distance of the burst, we obtain the peak flux density:

$$F_{\nu,\text{max},2} \simeq 0.11 \epsilon_B^{-1/2} L_{k,50}^{3/2} y_1^{-3} (t + \delta t)_2^{3/2} D_L^{-2} \text{Jy},$$

and

$$F_{\nu,\text{max},3} \simeq 1.6 \times 10^{-3} \epsilon_B^{-1/2} L_{k,50}^{-1/3} y_2^{1/2} (t + \delta t)_2^{1/2} D_L^{-1} \text{Jy}.$$  (16)

According to Equations (A1) and (A2) (Sari et al. 1998), the synchrotron spectrum of region 2 in the slow cooling regime ($\nu_{m,2} < \nu_{c,2}$) is described by $F_{\nu,2} = F_{\nu,\text{max},2} (\nu/\nu_{m,2})^{-(p-1)/2}$ for $\nu_{m,2} < \nu < \nu_{c,2}$ and $F_{\nu,2} = F_{\nu,\text{max},2} (\nu/\nu_{c,2})^{-(p-1)/2}(\nu/\nu_{c,2})^{-p/2}$ for $\nu > \nu_{c,2}$ or in the fast cooling regime ($\nu_{c,2} < \nu_{m,2}$) by $F_{\nu,2} = F_{\nu,\text{max},2} (\nu/\nu_{c,2})^{-1/2}$ for $\nu_{c,2} < \nu < \nu_{m,2}$ and $F_{\nu,2} = F_{\nu,\text{max},2} (\nu/\nu_{m,2})^{-1/2}(\nu/\nu_{m,2})^{-p/2}$ for $\nu > \nu_{m,2}$. In the fast cooling regime of region 3, $F_{\nu,3} = F_{\nu,\text{max},3} (\nu/\nu_{c,3})^{-1/2}$ for $\nu_{c,3} < \nu < \nu_{m,3}$ and $F_{\nu,3} = F_{\nu,\text{max},3} (\nu/\nu_{m,3})^{-1/2}(\nu/\nu_{m,3})^{-p/2}$ for $\nu > \nu_{m,3}$.
2.3. IC Emission from Two Shocked Regions

The ratio of IC to synchrotron emission luminosity $Y_i$ has been mentioned above (Figure 1). Although regions 2 and 3, formed during the two-shell collision, are optically thin to electron scattering, some synchrotron photons will be Compton scattered by shock-accelerated electrons, producing an additional IC component at higher-energy bands. Considering the highest energy electrons whose scattering enters the Klein–Nishina (KN) regime, the KN break frequency is calculated from

$$h
ν_{\text{KN}}^{\text{SSC}} = \frac{γ^2 m_e^4 c^6}{hν_{\text{m, KN}}} \sim 13 g_p^2 \frac{e^{-2}}{e^{-1/2} b_{-3/2}} \times L_{k,50}^{-1/2} γ_{1,1}^6 (t + δt)^{1/2} \text{ GeV.} \quad (17)$$

Based on the characteristic frequency $hν_{\text{m, KN}} \sim 1 \text{ keV}$ and $γ_{\text{e, m, KN}} \sim 10^5$, we can obtain $γ_{\text{e, m, KN}}/(m_e c^2) \sim 1$. So in the analysis estimates, it is reasonable to use the Thomson optical depth of the electrons in regions 2 and 3, which can be calculated by $τ_e = (σ_T n_e c^2)/(4π R^2)$, where $i = 2$ or 3. We calculate the upscattering spectral characteristic frequencies of the IC process as in Sari & Esin (2001). Region 3 is in the fast cooling regime and its SSC break frequencies become

$$h ν_{\text{m, 3}}^{\text{SSC}} = 2γ^2 γ_{\text{e, e, m, 3}} hν_{\text{m, 3}} \sim 2 g_p^2 \frac{e^{-2}}{e^{-1/2} b_{-3/2}} \times L_{k,50}^{1/2} γ_{1,1}^{6} (t + δt)^{1/2} \text{ GeV,} \quad (18)$$

and

$$h ν_{\text{e, 3}}^{\text{SSC}} = 2γ^2 γ_{\text{e, e, e, 3}} hν_{\text{e, 3}} \sim 2.1 γ_0^4 γ_{\text{e, B, 3}}^{-1/2} L_{k,50}^{-1/2} γ_{1,1}^{18} (t + δt)^{1/2} \text{ GeV.} \quad (19)$$

Obviously, the SSC peak energy for region 3 is in the KN regime and $h ν_{\text{m, 3}}^{\text{SSC}}$ is comparable with $h ν_{\text{e, 3}}^{\text{SSC}}$. As Tavecchio et al. (1998) suggested, whether or not the SSC peak frequency enters the KN regime, the spectral index of the SSC emission at the low-energy band has the same power-law approximation as the synchrotron emission. So the SSC flux of the fast-cooling region 3 $F_{\text{SSC}} = F_{\text{SSC,m, 3}}/(ν_{\text{SSC,m, 3}}^{1/2})$ for $ν_{\text{SSC,m, 3}} < ν < ν_{\text{crit}}$, where $ν_{\text{crit}} \sim \text{min}(ν_{\text{SSC,m, 3}}, ν_{\text{SSC,KN}, 3})$. As a result, the peak flux at $ν_{\text{SSC,KN}, 3}$ is

$$[ν F_ν]_{p, 3}^{\text{SSC}} = ν_{\text{SSC,KN}, 3}^{\text{SSC}} y_3 F_{\text{ν, max, 3}} \left(\frac{ν_{\text{SSC,KN}, 3}^{\text{SSC}}}{y_{\text{c, 3}}}\right)^{-1/2} \sim 6.7 \times 10^{-9} \frac{g_p}{0.1} \frac{e^{-2}}{e^{-1/2} b_{-3/2}} \times L_{k,50}^{-1/2} γ_{1,1}^{6} L_{D,28}^{-2} \text{ erg cm}^{-2} \text{ s}^{-1}. \quad (20)$$

Region 2 is in the slow cooling regime. Its SSC break frequencies are $ν_{\text{SSC,m, 2}} = 2γ^2 γ_{\text{e, e, m, 2}} hν_{\text{m, 2}} \sim 8.1 \times 10^{16} g_p^2 e^{-1/2} e^{-1/2} b_{-2/3} L_{k,50}^{1/2} γ_{1,1}^{6} (t + δt)^{1/2} \text{ Hz and } ν_{\text{SSC,e, 2}} = ν_{\text{SSC,m, 2}}$. Thus, we can obtain a very low peak flux

$$[ν F_ν]_{p, 2}^{\text{SSC}} = ν_{\text{SSC, e, 2}} \frac{y_2 F_{\text{ν, max, 2}} \left(ν_{\text{SSC, e, 2}}^{\text{SSC}} \right)^{(p-1)/2}}{ν_{\text{SSC, m, 2}}^{\text{SSC}}} \sim 10^{-11} \frac{g_p}{0.1} \frac{e^{-3}}{e^{-1/2}} \times L_{k,50}^{-1/2} γ_{1,1}^{6} L_{D,28}^{-2} \text{ erg cm}^{-2} \text{ s}^{-1}, \quad (21)$$

where $p = 2.5$ is assumed. Obviously, the SSC radiation of region 2 is much weaker than that of region 3.

Apart from the SSC scattering processes in regions 2 and 3, two other cross-IC scattering processes are also presented. Assuming the thin shell approximation, about one-half of the photons produced in one shocked region will diffuse into the other one in the comoving frame. We can obtain the low and high characteristic frequencies in the following cases. (1) The synchrotron photons in region 2 are scattered by electrons in region 3,

$$ν_{\text{CIC, L, 2}} = 2γ^2 γ_{\text{e, e, m, 2}} hν_{\text{m, 2}} \sim 1.76 \times 10^{16} γ_0^2 \frac{e^{-2}}{e^{-1/2} b_{-3/2}} \times L_{k,50}^{−1/2} γ_{1,1}^{6} \left(ν_{\text{SSC, m, 3}}\right)^{1/2} \text{ Hz,} \quad (22)$$

and the peak flux at $ν_{\text{CIC, L, 2}}$ can be estimated to be $[ν F_ν]_{\text{CIC, L, 2}} \sim 1 \times 10^{-9} \text{ erg cm}^{-2} \text{ s}^{-1}$. (2) The synchrotron photons in region 3 are scattered by electrons in region 2,

$$ν_{\text{CIC, L, 2}} = 2γ^2 γ_{\text{e, e, m, 3}} hν_{\text{m, 3}} \sim 1.76 \times 10^{16} γ_0 \frac{e^{-2}}{e^{-1/2} b_{-3/2}} \times L_{k,50}^{−1/2} γ_{1,1}^{6} \left(ν_{\text{SSC, m, 3}}\right)^{1/2} \text{ Hz,} \quad (23)$$

and the peak flux at $ν_{\text{CIC, L, 2}}$ can be estimated to be $[ν F_ν]_{\text{CIC, L, 2}} \sim 1 \times 10^{-9} \text{ erg cm}^{-2} \text{ s}^{-1}$. From the above equations and Figure 3, for synchrotron emission, region 3 is more important than region 2. For IC emission, we can also see that the SSC emission of region 3 is the strongest among the IC components, while the SSC emission of region 2 is the weakest. This is very easy to understand, since the electrons in region 3 have larger Lorentz factors due to RRS while the electrons in region 2 have smaller Lorentz factors due to NPS.

3. APPLICATION TO GRB 100728A AND NUMERICAL CALCULATIONS

3.1. Parameter Limits

The Fermi/GBM triggered GRB 100728A at 02:17:31 UT, 53.6 s before the Swift/BAT trigger. The duration of this burst is $T_{90} \sim 163$ s. Several apparent X-ray flares were observed by Swift/XRT, while significant GeV photons were detected by Fermi/LAT during the early afterglow phase. We can obtain the observed properties of this GRB. (1) From XRT, the time-averaged spectrum of these flares from $t \sim 167$ s to 854 s can
Figure 3. Time-resolved spectra of the six components at $t = 10$ ms. The green dotted line and dashed line represent the synchrotron emission of regions 2 and 3, respectively. The wine short-dotted line and short-dashed line represent the SSC emission of regions 2 and 3, respectively. The orange dash-dot-dotted line and short-dash-dotted line represent the CIC emission, respectively. The same parameters as in Figure 1 are taken in numerical calculations.

(A color version of this figure is available in the online journal.)

Figure 4. Time-averaged spectra of the X-ray and GeV emission of GRB 100728A and fitting this burst with our model. The observed data are taken from Abdo et al. (2011), which are fitted by a time-averaged spectrum from $t = 0$ s to $t = 10^{1.8}$ s. The green dotted line and dashed line represent the synchrotron emission of regions 2 and 3, respectively. The wine short-dotted line and short-dashed line represent the SSC emission of regions 2 and 3, respectively. The orange dash-dot-dotted line and short-dash-dotted line represent the CIC emission, respectively. The blue thin solid line represents the total IC including SSC and CIC, and the red thick solid line represents the sum of synchrotron and IC emission. The other parameters $L_{k,1} = 7.0 \times 10^{50}$ erg s$^{-1}$, $L_{k,4} = 2.5 \times 10^{50}$ erg s$^{-1}$, $\gamma_1 = 50$, $\gamma_4 = 5830$, $p = 2.48$, $\epsilon_e = 0.3$, $\epsilon_B = 0.03$, $\theta_{j0} = 0.1$, and $z = 1$ are taken in numerical calculations.

(A color version of this figure is available in the online journal.)

be well fitted by the Band function (Band et al. 1993) with a low-energy slope of $\alpha = -1.06 \pm 0.11$, a high-energy slope $\beta = -2.24 \pm 0.02$, and a peak energy $E_{pk} = 1.0^{+0.8}_{-0.4}$ keV (Abdo et al. 2011). (2) From LAT, the spectrum of the GeV emission is well fitted with a photon index of $\Gamma_{LAT} = -1.4\pm0.2$ (1σ) (Abdo et al. 2011) and the flux $F_{LAT} \sim (5.8\pm4.5) \times 10^{-9}$ erg cm$^{-2}$ s$^{-1}$ (He et al. 2012) during the period $t \sim 167$ s to 854 s. We use our model with reasonable parameters to fit the GRB 100728A time-averaged energy spectrum (Figure 4). The data points in this figure are taken from Abdo et al. (2011), from $T_0 + 254$ s to $T_0 + 854$ s for about seven flares, where $T_0$ is the trigger time. The duration of one flare is approximately tens of seconds. Taking into account the similarity among the flares generated, to fit the interval data we only model one flare induced by a collision between two shells, so we choose the time from the onset of the two-shell interaction, i.e., $t = 0$ s to $t = 10^{1.8}$ s,
where the latter time is comparable to the duration of one flare of GRB 100728A.

The emission of region 3 is the most important and is used to explain the observations of GRB 100728A. Since region 3 is in the fast cooling regime and the high-energy slope $\beta = -2.24 \pm 0.02$, we can obtain the electron distribution index $p = 2.48 \pm 0.04$. For $v_m < v < v_{m,3}$ and $v_{SSC,3} < v < v_{crit}$, the synchrotron spectrum and SSC component of an X-ray flare have the same photon index of $-3/2$, which is consistent with the observed GeV emission, $\Gamma_{LAT} = -1.4 \pm 0.2$. The low-energy slope of $\alpha = -1.06 \pm 0.11$, which may be caused by the low frequency absorption effect, can also be regarded as a consistent result within the acceptable range.

In the two-shell collision model, we only regard the kinetic-energy luminosity $L_4$, and Lorentz factors $\gamma_1$ and $\gamma_4$ as variable parameters. Since $h\nu_{m,3} \sim E_{pk} = 1.0^{+0.8}_{-0.4}$ keV and $h\nu_{m,3} \sim h\nu_{SSC,3} \sim h\nu_{LAT,3} > 10$ GeV, based on the ratio of Equations (12) and (18), $\gamma_4/\gamma_1 > 30$ is required, which is consistent with the dynamical analysis. This suggests that the posterior shell can catch up with the prior shell very soon and an NFS and RRS can be formed. Furthermore, according to Equation (20) and $F_{LAT,3} \sim (5.8 \pm 4.5) \times 10^{-9}$ erg cm$^{-2}$ s$^{-1}$, we obtain $L_K \sim 0.9 \pm 0.8 \times 10^{50}$ erg cm$^{-2}$ s$^{-1}$. Finally, for Equation (12) and $h\nu_{m,3} \sim E_{pk} = 1.0^{+0.8}_{-0.4}$ keV, we can obtain $\gamma_4/\gamma_1 \sim f_0$, which is an essential condition to produce a bright X-ray flare.

In addition, the optical depth due to pair production can be calculated by (Lithwick & Sari 2001)

$$\tau_{\gamma\gamma} = \frac{(11/180)\sigma_T N_{\gamma m,an}}{4\pi R^2},$$

where $N_{\gamma m,an}$ is the photon number with a frequency up to $v_{m,an}$ with $h\nu_{m,an} \equiv (\gamma m_e C^2 / h) / h\nu_{m,an}$ which can annihilate the $v_m \sim 1$ keV photons. So $N_{\gamma m,an} \approx L_{GeV} / (h\nu_{m,an})$ can be used to estimate the photon number with frequency up to $v_{m,an}$, where $L_{GeV}$ is the GeV luminosity. Furthermore, $R = 2\gamma^2 c \delta t \sim 2 \times 10^{14}$ cm, so we calculate

$$\tau_{\gamma\gamma} \sim 2 \times 10^{-3} L_{GeV} \delta t \gamma^6 \delta t \gamma^2 \cdot t_1,$$

which indicates that the pair production effect is unimportant. As a result, the secondary electrons produced by the pair production effect are ignored here.

To summarize, the GeV emission of GRB 100728A can be well described by the IC process of the electrons accelerated by forward–reverse shocks in regions 2 and 3. Using reasonable and appropriate values of the model parameters, we present good fitting results (Figure 4).

3.2. Numerical Calculations of the Model

The results mentioned above are analytical estimates, but all the figures in this paper, except for Figures 1 and 2, are based on more detailed and precise numerical calculations. Next, we will describe our numerical methods.

As mentioned above, the electrons accelerated by the shocks are assumed to have a power-law energy distribution, $dn_e'/d\gamma_e' \propto \gamma_e'^{-p}$ for $\gamma_e' > \gamma'_e,m$, where $\gamma'_e,m$ is the minimum Lorentz factor. When the electron cooling effect is considered, the resulting electron distribution in the comoving frame takes the following forms. (1) If the newly shocked electrons cool faster than the shock dynamical timescale, i.e., fast cooling ($\gamma'_e,m > \gamma'_e,c$),

$$\frac{dn_e'}{d\gamma_e'} \propto \begin{cases} \gamma_e'^{-2} & \gamma_e' > \gamma'_e,m \\\n \gamma_e'^{-p} & \gamma_e' < \gamma'_e,m \end{cases}$$

(2) If the newly shocked electrons cool slower than the shock dynamical timescale, i.e., slow cooling ($\gamma'_e,m \leq \gamma'_e,c$),

$$\frac{dn_e'}{d\gamma_e'} \propto \begin{cases} \gamma_e'^{-p} & \gamma_e' < \gamma'_e,m \\\n \gamma_e'^{-p-1} & \gamma_e' < \gamma'_e,c \end{cases}$$

where $\gamma'_e,max$ is the maximum Lorentz factor of the shocked electrons in the comoving frame, which is determined by equating the electron acceleration timescale with the timescale of the non-thermal emission (including synchrotron and IC emission) cooling timescale.

From the electron distribution, the synchrotron seed photon spectrum can easily be obtained (Rybczki & Lightman 1979). After we obtain the electron distribution and the seed photon spectrum, the emission of seed synchrotron photons being upscattered by relativistic electrons that are accelerated by forward–reverse shocks can be computed. For simplicity, we only consider the first-order IC and neglect the higher-order IC processes. In the Thomson regime, therefore, the IC volume emissivity in the comoving frame can be given by (Rybczki & Lightman 1979; Sari & Esin 2001)

$$f'_{IC} = 3\sigma_T \int_{\gamma_{e,m}}^{\gamma_{e,max}} d\gamma_e' \frac{dn_e'}{d\gamma_e'} \frac{\gamma_e'}{c^2} \int_0^1 dx \frac{f_{\nu'}}{g(x)} \frac{f_{\nu'}}{f_{\nu}},$$

where $x = \nu'/(4\gamma_e'^2 v_s')$, $v_s'$ is the synchrotron seed photon frequency in the comoving frame, $f_{\nu'}(x)$ is the incident-specific flux at the shock front in the comoving frame, and $g(x) = 1 + x + 2x \ln x - 2x^2$ considers the angular dependence of the scattering cross section in the limit $\gamma_e' \gg 1$ (Blumenthal & Gould 1970; Sari & Esin 2001). We can convert the comoving-frame quantities to observed quantities by considering $f'_{IC} = f_{IC} 4\pi R^2 \Delta R' / 4\pi D^2$ and $f_{\nu'} = f_{\nu'} 4\pi R^2 / 4\pi D^2$, where $R$ is the shock radius, $D$ is the distance to the observer, and $\Delta R'$ is the comoving width of the shocked shell (Sari & Esin 2001; Wang et al. 2001b). So we obtain the IC flux in the observer frame,

$$f_{IC} = 3\Delta R' \sigma_T \int_{\gamma_{e,m}}^{\gamma_{e,max}} d\gamma_e' \frac{dn_e'}{d\gamma_e'} \frac{\gamma_e'}{c^2} \int_0^1 dx \frac{f_{\nu'}}{g(x)} f_{\nu}(x).$$

If $\gamma_e' h\nu_s' \gg m_e c^2$, then the KN regime should be considered.

Equation (30) can be replaced by (Blumenthal & Gould 1970)

$$f_{IC} = 3\sigma_T \int_{\gamma_{e,m}}^{\gamma_{e,max}} d\gamma_e' \frac{dn_e'}{d\gamma_e'} \frac{\gamma_e'}{c^2} \int_0^1 dx \frac{f_{\nu'}}{g(x)} \frac{f_{\nu'}}{f_{\nu}} \frac{1 + x + 2x \ln x - 2x^2}{2} \left(1 - x \right),$$

where $y = 4\gamma_e' h\nu_s' / (m_e c^2)$ and $x = h\nu_s' / (y(\gamma_e' m_e c^2 - h\nu_s')) = \nu'/ (4\gamma_e'^2 v_s' - v_s')$.

3.3. Light Curves of the Model

We now calculate synchrotron and IC emission light curves. We can predict that both emissions will have a good temporal coincidence, because they are produced from the same region. This may be the most important difference from the EIC model, because in the latter model, the GeV emission will last for a period much longer than the duration of the GeV emission based on the curvature effect of an external forward shock and
is mainly extended by the highly anisotropic radiation of the upscattered photons.

Yu & Dai (2009) presented the theoretical X-ray flare light curves produced by considering a collision of two homogeneous shells. Here, we give both X-ray and GeV emission light curves based on more precise numerical calculations in our assumed dynamics in Figure 5. A basic characteristic of the X-ray flare is that its light curve has a rapid rise and fall. The rapid rise can clearly be seen by resetting the time zero point in the right panel of Figure 5. Before the two shocks’ crossing time $T_{crs}$, ignoring possible spreading of the hot shocked materials, the evolutions of $V_{c, i}$, $v_{m, i}$, and $F_{v, max, i}$ follow Equations (11), (12), (13), (15), and (16). After $T_{crs}$, the spread of the hot materials into the vacuum cannot be ignored and the merged shell experiences adiabatic cooling. During this phase, a simple power law of the volume of the merged shell is assumed to be $V_i' \propto R^2$, where $s$ is a free parameter and its value is taken to be from 2 to 3. As a result, the particle number densities would decrease as $n_i' \propto V_i'^{-4/3} \propto R^{-4s/3}$, the internal energy densities as $\varepsilon_i' \propto V_i'^{-4/3} \propto R^{-4s/3}$, and the magnetic field strength as $B_i' \propto (\varepsilon_i')^{-1/2} \propto R^{-2s/3}$. From Equation (4), before $\delta t$, any increase of the radius $R$ can be ignored (i.e., $R \simeq$ constant), but after $\delta t$, the radius increases linearly with time (i.e., $R \propto t$). For simplicity, we consider $T_{crs} \simeq \delta t$. So the characteristic quantities can be presented as

$$v_{m, i} \propto \begin{cases} t^0 & t < T_{crs} \\ t^{-2/3} & t > T_{crs} \end{cases}$$

$$v_c \propto \begin{cases} t^{-2} & t < T_{crs} \\ t^3 & t > T_{crs} \end{cases}$$

and

$$F_{v, max} \propto \begin{cases} t^{-2/3} & t < T_{crs} \\ t & t > T_{crs} \end{cases}$$

For clarity, the subscript $i$ is omitted. The theoretical light curve of an X-ray flare has been given in the Appendix.

The intrinsic decline slope of the last segment of the theoretical light curves is $\alpha = (sp + s)/3$, where $\alpha = -d \log F_c/d \log t$. Liang et al. (2006) found that the rapid decline of most X-ray flares seems to be consistent with the curvature effect from fitting the light curves of X-ray flares detected by Swift and that the temporal index is equal to the simultaneous spectral index plus 2. In the last segment of the theoretical light curves, the corresponding spectral index is $(p - 1)/2$ for $v_{m, i} < v_{X, m} < v_c$, where $v_{X, m} \sim 10^{17}$ Hz. For $s = 3$ and $2 < p < 3$, we find

$$\alpha = \frac{3p + 3}{3} > \frac{p - 1}{2} + 2.$$  (36)

So the X-ray flux would have a rapid decline owing to the curvature effect.

Similarly, in the left panel of Figure 5, several apparent power-law forms are written as

$$F_v \propto \begin{cases} t & T_m < t < T_{crs} \\ t^{-\frac{p-1}{3}} & T_{crs} < t < T_m \\ t^{-\frac{p-1}{3}+1} & t > T_m \end{cases}.$$  (37)

The temporal index $\alpha$ of the last segment of the light curves is $(sp - 2s + 3)/3$. Although this temporal index cannot easily satisfy Equation (36), it cannot be ruled out absolutely. This is because the segment near the flare onset time may be steepened by the time zero effect dramatically. This effect can be seen by comparing the right panel with the left panel of Figure 5, where the right panel resets the time zero point, having a larger slope. So X-ray flares formed by two-shell interactions are characteristic of a rapid rise and fall.

In Figure 5, the X-ray and GeV emission have a similar evolution with time, which can easily be seen in the right panel.

4. CONCLUSIONS

In this paper, the late internal shock origin for X-ray flares is adopted, and a collision of two homogeneous shells is analyzed in quantitative calculations. Besides this model, X-ray flares may also be produced by a delayed external shock (Piro et al. 2005; Galli & Piro 2007). Both models suggest a prolonged central engine activity. Wu et al. (2005) performed a quantitative analysis in two cases, and suggested that two kinds of X-ray flares are not excluded, and may even coexist for a certain GRB.
The Astrophysical Journal, 772:152 (8pp), 2013 August 1

The strong SSC and CIC emission during X-ray flares was analyzed and found to be detectable with high-energy telescopes (Fan et al. 2008; Yu & Dai 2009). GRB 100728A is the second case (after GRB 090510) to date with simultaneous Swift and Fermi observations in which the GeV and X-ray emission may have the same origin because of their temporal coincidence. Thus, the afterglow synchrotron and SSC emission scenarios may be slightly far-fetched. It is natural that high-energy emission can be generated during X-ray flares by IC processes. He et al. (2012) provided an explanation for GRB 100728A in the EIC scenario, in which X-ray flare photons are upscattered by electrons in an external forward shock. Here, we give an alternative reasonable explanation by using the SSC and CIC scenario where X-ray flare photons are upscattered by electrons accelerated by forward–reverse shocks in the late internal shock scenario where X-ray flare photons are upscattered by electrons in an external forward shock. Here, we give an alternative reasonable explanation by using the SSC and CIC scenario where X-ray flare photons are upscattered by electrons accelerated by forward–reverse shocks in the late internal shock scenario. One main difference between the two scenarios is whether there is a good temporal correlation between X-ray and GeV emission (Fan et al. 2008). In the SSC and CIC scenario, a good temporal correlation between X-ray and GeV emission is expected (Figure 5), whereas GeV photons in the EIC scenario may have a significant temporal extension and even last much longer than one X-ray flare (Fan et al. 2008). So, no obvious temporal extension of GeV photons for GRB 100728A supports the SSC and CIC scenario. In fact, neither the SSC and CIC scenario nor the EIC scenario are excluded and may coexist in the EIC scenario may be too weak (compared with that in the SSC and CIC scenario) to be detected.

We thank the referee for helpful comments and constructive suggestions that have allowed us to improve the manuscript significantly, and Yunwei Yu for useful discussions. This work was supported by the National Natural Science Foundation of China (grant No. 11033002).

APPENDIX

Here, we present the theoretical X-ray flare light curves in the parameters of Figure 2. The synchrotron energy spectrum can be obtained from Sari et al. (1998). (1) In the fast cooling regime, the energy spectrum is described by

\[ F_\nu = \begin{cases} 
(\nu/\nu_c)^{1/3} F_{\nu,\text{max}} & \nu < \nu_c \\
(\nu/\nu_m)^{-1/2} F_{\nu,\text{max}} & \nu_c < \nu < \nu_m \\
(\nu/\nu_m)^{-p/2} (\nu_m/\nu_c)^{-1/2} F_{\nu,\text{max}} & \nu_m < \nu.
\end{cases} \]  

(A1)

(2) And for slow cooling, the energy spectrum reads

\[ F_\nu = \begin{cases} 
(\nu/\nu_m)^{1/3} F_{\nu,\text{max}} & \nu < \nu_m \\
(\nu/\nu_m)^{-(p-1)/2} F_{\nu,\text{max}} & \nu_m < \nu < \nu_c \\
(\nu/\nu_c)^{-p/(p-1)} (\nu_c/\nu_m)^{-(p-1)/2} F_{\nu,\text{max}} & \nu_c < \nu.
\end{cases} \]  

(A2)

For a specific X-ray band in Figure 2, from Equations (33)–(35), the theoretical X-ray flare light curves can be given by

\[ F_\nu \propto \begin{cases} 
t & t < T_{cm1} \\
t^{5/3} & T_{cm1} < t < T_{c1} \\
t^0 & T_{c1} < t < T_{crs} \\
t^{\nu_c/\nu_m} & T_{crs} < t < T_m \\
t^{(\nu_c/\nu_m)-1} & T_m < t < T_{cm2} \\
t^{-(\nu_c/\nu_m)-1} & T_{cm2} < t < T_{c2} \\
t^{-3} & t > T_{c2}.
\end{cases} \]  

(A3)

where \( T_{cm1} \) (\( T_{cm2} \)) is the first (second) time \( t_c = \nu_m \), and \( T_m \) (\( T_{c1} \) or \( T_{c2} \), \( T_{crs} \) for the first time and \( T_{c2} \) for the second time) is the time of the break frequency \( \nu_m(t_c) \) passing through the X-ray band (about \( 10^{17} \) Hz) in region 3. It should be pointed out that there may be a mistake in Yu & Dai (2009), which gave the temporal index \((sp + 3)/3 < t > T_{c2}\).
