**INTRODUCTION**

Fructose consumption has recently been compared with alcohol in terms of its adverse effects on health. Fructose consumption per capita in the western world has increased at a steady rate since the 1950s, mainly fueled by an almost fivefold increase in consumption of soft drinks sweetened with 10% to 15% sucrose or high-fructose corn syrup. This increased fructose ingestion has been linked in particular with obesity and type 2 diabetes, but is also considered as a risk factor in the development of dementia and a high-fructose intake is associated with impaired cognitive function in humans. Recently, a high-fructose intake in rats, coupled with a low omega-3 fatty acid intake, was observed to induce a metabolic syndrome like state in the brain as well as impaired cognitive function suggesting an interaction between fructose intake and brain function.

The last few decades it has become apparent that the fetal and early life nutrition and environment can permanently change the phenotype of the adult organism, a phenomenon termed as fetal programming, but more recently also termed as developmental programming, implying that fetal programming may in fact involve changes in normal development. Thus, a low birth weight has been observed with a maternal high-fructose diet indicating possible developmental programming effects by a high maternal fructose intake. Taken together, these findings indicate that a high maternal fructose intake during gestation may well impact fetal growth in general as well as brain development and possibly brain function in adulthood of the offspring.

Thus, we hypothesized that feeding pregnant rats a diet with high-fructose content during gestation and lactation would affect brain mitochondrial function in late adult life of the offspring.

**MATERIALS AND METHODS**

Animals

All experimental procedures complied with guidelines laid down by The Danish Animal Experiments Inspectorate (permit 2013-15-2934-00904) and by the local animal facility at the University of Copenhagen, Denmark and were performed according to the ARRIVE (Animal Research: Reporting In Vivo Experiments) guidelines. Female Fischer F344 rats (N = 12) were obtained from Harlan Laboratories (Horst, The Netherlands) on day 1 of pregnancy and randomly assigned to two different dietary groups (ensuring an equal weight distribution per group) receiving either a high-fructose diet or a control diet (Research Diets Inc., New Brunswick, NJ, USA; Table 1) during gestation and the subsequent lactation period. The offspring was weighed <2 hours after birth and litter sizes normalized to N = 8 per dam. After weaning (day 20 after birth), both groups of offspring were randomly reduced to 8 per group, with at least one pup taken from the litter of each dam, and all animals were put on a standard chow diet (Altromin 1319F; Altromin, Lage, Germany) for the rest of their lives. An Echo MRI 4-in-1 for Small Animals (EchoMRI, Houston, TX, USA) was used to monitor total body fat mass and lean mass of unanesthetized animals at 15 months of age. Body weights were measured once a week and snout–anus

Maternal fructose and offspring brain mitochondria

OH Mortensen et al.

length measured post mortem at 15 months using a standard ruler. Offspring food and water intake was not monitored. One animal in the fructose group died during experimental procedures and one animal from each group died due to unknown causes between 12 and 15 months of age. The resulting animals (7 controls and 6 fructose exposed offspring) were killed at 15 months of age after an overnight fast and brain tissue removed for further analysis as described below.

The rat strain chosen for this study, the Fischer 344 strain, is the most used strain in aging research and seems to be the preferred rat model in cognitive aging research. We chose it primarily as its life expectancy is significantly shorter than common outbred rat strains, and as a consequence has a tendency to be more pronounced in late adult life.

Preparation of Isolated Mitochondria
Mitochondria were isolated from brain (without the cerebellum) as previously described by Rosenthal et al. using a discontinuous Percoll gradient centrifugation. Overnight fasted rats were sedated with a mixture of Hypnorm (active ingredients fentanyl and fluanisone at a concentration of 0.079 and 2.5 mg/mL, respectively) and Dormicum (active ingredient midazolam at a concentration of 1.25 mg/mL) in water given by intraperitoneal injection, 15 minutes before they were killed at 15 months of age after an overnight fast and brain tissue removed for further analysis as described below.

RNA Isolation, Quantitative Real-Time PCR, and Affymetrix Microarrays
RNA was extracted from 20 to 30 mg brain tissue using Qiagen (Valencia, CA, USA) together with a Qiagen TissueLyzer (Qiagen), as described by the manufacturer, followed by cDNA synthesis from 1.5 μg RNA in a 20-μL volume using the High Capacity cDNA Reverse Transcription Kit with RNase inhibitor and random hexamer primers (Applied Biosystems). A nonreverse transcription and a nontemplate control reaction were included and the cDNA product was diluted to a volume of 200 μL and stored at −20 °C until further analysis.

Mitochondrial Respiration
Mitochondrial function was tested using Oroboros Oxygraph-2K instruments (Oroboros Inc., Innsbruck, Austria) operating eight oxygraph chambers in parallel at 25 °C. Briefly, 20 μL mitochondrial suspension was added to 2 mL of incubation buffer (125 mM/L KCl, 20 mM/L Hepes, 2 mM/L K2HPO4, 1 mM/L MgCl2, 0.1 mM/L EGTA, 0.025% BSA (FFA free), pH 7.0 at room temperature) in each chamber. Stirrer speed was 600 r.p.m. Approximately 5 minutes after the mitochondria were introduced into the chambers, malate and pyruvate were added to concentrations of 1 and 0.5 mM/L, respectively to achieve state 4 respiration. Once a steady-state 4 respiration was observed, a small known amount of ADP (0.4 μmol) was added to initiate state 3 respiration and to estimate the P/O ratio. Subsequently, state 3 respiration was reestablished by raising the ADP concentration to 2.0 mM/L followed by the addition of succinate (5 mM/L) to involve full complex II contribution to respiration. To conclude the experiment, the complex I inhibitor rotenone was added to a final concentration of 50 μmol/L. All measurements were performed in duplicate. Between experiments the chambers were washed twice with ethanol and water. All mitochondrial preparations had respiratory control ratios (RCR, state 3 with pyruvate/state 4) above 16, indicating consistent preservation of mitochondrial function after isolation.

Gene Expression Microarrays

For gene expression profiling by microarrays, RNA isolated by Qiazol from 15-month-old Fischer rats as described above was further purified using the RNeasy kit (Qiagen) and the quality of RNA assured using a Bioanalyzer (Agilent, Santa Clara, CA USA) as described by the manufacturer (all samples had an RIN of >8.0). The samples were analyzed at the RH Microarray Center (Center of Genomic Medicine, Rigshospitalet, Copenhagen, Denmark) with cDNA prepared using the Ambion WT Expression Kit (Life Technologies, Paisley, UK) and cDNA labeling performed using the Affymetrix Whole Transcript (WT) Expression Kit (Affymetrix Inc., Santa Clara, CA, USA) before being analyzed on GeneChip Rat Gene 1.0 ST Arrays (Affymetrix) according to the manufacturer’s instructions. The microarrays were analyzed using R 3.0.1 (open source: http://www.r-project.org) and Bioconductor 2.12 (open source: http://www.bioconductor.org). Raw CEL files for all samples were normalized using quantile normalization and log2 probe expression values were obtained using the Robust Multi-array Average method with default parameters in R/Bioconductor. The expression level threshold (detection limit) for the arrays was set to the median of the antigenomic (negative controls) probe set expression levels ± s.d. and calculated for each sample. Starting out with 29,214 probe sets, control probesets, and probesets not detected on at least 50% of the arrays in each group were removed resulting in 10,288 probesets. This was further refined by removing unknown genes resulting in 8,980 known genes (Supplementary Table). We examined whether any genes were changed significantly between the control and gestational fructose group using SAM (Significance Analysis of Microarrays) and found no differences. To examine whether any gene sets were significantly changed we employed GSA20 and GSEA21 using gene sets from MSigDB v4.0 (Molecular Signatures Database, Broad Institute, Cambridge, MA, USA; http://www.broadinstitute.org/gsea/msigdb) and found no differences. To obtain the mitochondrial genes, the 8,980 known genes were filtered by selecting all broadinstitute.org/gsea/msigdb) and found no differences. To obtain the mitochondrial genes, the 8,980 known genes were filtered by selecting all

Western Blotting

Twenty micrograms of mitochondrial protein of each sample was subjected to SDS-PAGE (4% to 12% Bis-Tris precast gels, NuPage) followed by electroblotting onto a PVDF membrane. The membrane was blocked for 1 hour at 5% skim milk in Tris-Buffered Saline containing 0.1% Tween-20 (TBS-T) followed by incubation overnight with an affinity-purified rabbit antibody against rat UCP5 (UCP51-A; Alpha Diagnostic Intl. Inc., San Antonio, TX, USA) at a 1:250 dilution in 5% skim milk in TBS-T and incubated overnight at 4°C. The membrane was washed in TBS-T and incubated for 1 hour at room temperature with horseradish peroxidase-conjugated anti-rabbit (Dako, Glostrup, Denmark) diluted 1:1000 in 5% skim milk in TBS-T. After washing, specific binding was detected using SuperSignal West Femto Chemiluminescent Substrate (Thermo Scientific, Pierce Technology, Omaha, NE, USA) and visualized using a Syngene G-Box gel imaging system (Syngene, Cambridge, UK). Quantification was performed using the Image J gel analysis software (open source: http://rsbweb.nih.gov) and UCP5 protein amounts were normalized to the mean of the control samples. All buffers and gels were purchased from Invitrogen (Carlsbad, CA, USA).

Statistics

Differences between groups were tested by Student’s t-test. Correlation was tested using Pearson’s correlation using all data points. The mRNA data were log transformed to ensure a normal distribution. All statistical analyses were performed using SAS 9.2 (The SAS Institute, Cary, NC, USA). A P value of <0.05 was considered as significant while a P value between 0.05 and 0.1 was considered as a trend. A P value above 0.1 was considered as nonsignificant (NS). All data except mRNA levels are presented as means ± standard error of the mean (s.e.m.). The mRNA levels are presented as geometric means with 95% confidence intervals.

RESULTS

Dam and Offspring Physiologic Data

Pregnant rat dams were subjected to two different but isocaloric diet regimes from day 1 of pregnancy until the end of lactation (day 20 after birth): (1) a high-fructose diet (50% energy from fructose) and (2) a control diet (fructose exchanged with corn starch) (Table 1). The fructose group tended to have an increased food intake during pregnancy compared with control (P = 0.09) and had a significantly higher weight gain during gestation (E0-E20 body weight gain, P = 0.005) (Table 2). Nevertheless, there was no difference in birth weight or litter size between groups. Interestingly, the fructose exposed offspring displayed a lower body weight throughout life, except between 1 month (4 weeks) and 5 months (22 weeks) of age (Figure 1; Table 2), and had a

NS, nonsignificant. Pregnant Fischer F344 dams were subjected to either a control or a high-fructose diet during gestation and lactation and their male offspring was followed until 15 months of age where brain mitochondria were isolated. Figures are means ± s.e.m. * Indicates P < 0.05 compared with control rats by Student’s t-test. For male offspring data, N = 8 in both the control and fructose groups from 0 to 12 months. At 15 months, N = 7 for the control group and N = 6 for the fructose group.
significantly shorter snout–anus span at 15 months of age \((P = 0.035)\), while body fat and lean mass at the same time point were unaffected by gestational fructose exposure (Table 2).

Brain Mitochondria

The mitochondrial function was examined in isolated mitochondria (Table 3). With malate and pyruvate as substrates, the fructose exposed offspring showed unchanged state 4, but increased state 3 respiration from \(197 \pm 5.3\) to \(213 \pm 4.4\) nmol/min per mg mitochondrial protein \((P = 0.040)\) and similarly an increase from \(283 \pm 7.4\) to \(307 \pm 6.9\) nmol/min per mg mitochondrial protein \((P = 0.037)\) with malate, pyruvate, and succinate as substrates. When inhibiting complex I with rotenone, respiration was still higher in the fructose exposed offspring compared with controls \((182 \pm 4.1\) and \(168 \pm 4.5\), respectively, \(P = 0.048)\). Furthermore, the fructose exposed offspring exhibited a decrease in the \(P/O_2\) ratio \((P = 0.029)\) with malate and pyruvate as substrates.

Taken together, these results prompted us to examine the mRNA levels of the brain UCPs 1 to 5 by quantitative real-time PCR (Figure 2A). The mRNA levels of UCP1 and UCP3 were below the detection limit and there was no change in the mRNA levels of UCP2 and UCP4. However, we observed a tendency \((P = 0.09)\) toward an increase in UCP5 mRNA levels in the fructose offspring compared with control, and interestingly, we found a highly significant inverse correlation between UCP5 mRNA levels and the \(P/O_2\) ratio \((P = 0.008)\) (Figure 2B). There was, however, no correlation between \(P/O_2\) ratio and UCP2 or UCP4 mRNA levels (data not shown). The protein levels of UCP5 were similarly increased in the fructose offspring compared with control \((P = 0.032)\) (Figure 3A), and inversely correlated with the \(P/O_2\) ratio \((P = 0.034)\) (Figure 3B). This suggests that increased levels of UCP5 might be causally linked with the observed \(P/O_2\) ratio decrease. There was no difference in citrate synthase activity of the isolated brain mitochondria between the control and fructose exposed offspring (3.55 \(\pm\) 0.09 and 3.71 \(\pm\) 0.05 U \(\cdot\) (per mg mitochondrial protein), respectively, \(P = 0.16)\).

Brain Gene Expression Profiling

In an attempt to examine whether other genes might be able to explain the observed fetal programming effects of fructose exposure in early life, we also examined the brain gene expression

![Growth curves. Growth curves of Fischer F344 rat offspring subjected to either a control diet or a fructose diet during gestation and lactation. N = 7–8 and 6–8 for controls and fructose-fed animals, respectively.](image)

Figure 2. Levels of brain uncoupling protein (UCP) mRNA. (A) Brain mRNA levels of 15-month-old Fischer F344 rats subjected to either a control diet or a fructose diet during gestation and lactation. The mRNA levels were normalized to \(\beta\)-actin and are given as geometric means with 95% confidence intervals. ND, not detected. (B) Pearson’s correlation between log-transformed UCP5 mRNA levels and \(P/O_2\) ratios (see Table 3).

Table 3. Respiration rate and phosphorylation efficiency (\(P/O_2\) ratio) of isolated brain mitochondria

| Respiratory state and substrates | Control, \(N = 7\) | Fructose, \(N = 6\) | \(P\) |
|---------------------------------|-------------------|-------------------|------|
| State 4: 0.5 mmol/L pyruvate     | 10.4 \(\pm\) 0.4  | 11.1 \(\pm\) 0.2  | NS   |
| State 3: 0.5 mmol/L pyruvate + 2 mmol/L ADP | 197 \(\pm\) 5.3 | 213 \(\pm\) 4.4* | 0.040 |
| State 3: 5 mmol/L succinate     | 283 \(\pm\) 7.4  | 307 \(\pm\) 6.9*  | 0.037 |
| State 3: 5 mmol/L succinate + 50 \(\mu\)mol/L Rotenone | 168 \(\pm\) 4.5 | 182 \(\pm\) 4.1* | 0.048 |
| \(P/O_2\), pyruvate (mole ATP per mole oxygen) | 4.86 \(\pm\) 0.05 | 4.69 \(\pm\) 0.04* | 0.029 |

NS, nonsignificant. Mitochondria isolated from whole brain (without cerebellum) of 15-month-old Fischer F344 rats whose mothers were subjected to either a control diet or a high-fructose diet during gestation and lactation. Mitochondria were examined by high-resolution respirometry. The oxygen consumptions are given as nmol \(O_2/min\) \(\cdot\) (per mg mitochondrial protein). Malate (1 mmol/L) was present in all incubations in addition to the substrate additions indicated. Figures are means \(\pm\) s.e.m. * Indicates \(P<0.05\) compared with control rats by Student’s \(t\)-test.
and pyruvate as substrates. Thus, it would seem that respiration was increased to compensate for a lower ATP production caused by an enhanced UCP5 generated uncoupling. Accordingly, the actual state 3 ATP production was similar in the control and the fructose groups (1002 ± 17.9 and 954 ± 25.4 nmol/min per mg protein, respectively; calculated as the P/O ratio multiplied by the state 3 oxygen consumption; \( P = 0.16 \)). Recently, a decrease in overall P/O ratios in brain mitochondria was suggested to be related to a decrease in flux through Complex I of the electron transport chain.\(^{23}\) This seems at variance with our results, at least in the sense that gestational fructose exposure increased respiration also in the presence of rotenone (168 ± 4.5 and 182 ± 4.1 nmol/min per mg mitochondrial protein, respectively, Table 3).

While the observed changes in mitochondrial phosphorylation efficiency after fructose exposure are statistically significant, they are nominally small (4% to 9%). It may be argued that such a small change, in spite of being statistically significant, may not be significant in terms of brain function, and this aspect needs to be examined further. However, it should be noted that a recent study found a similar small change in the P/O ratio in aging rat brain compared with younger animals,\(^ {23}\) suggesting that even nominally small changes in mitochondrial efficiency may actually have a functional role in or be a marker of aging. Seen in this perspective we speculate that gestational fructose exposure may provoke/accelerate aging-related metabolic changes in the brain.

In rats, there seems to be a direct link between increased fructose intake in adult rats and impaired whole body metabolic function (hyperlipidemia and insulin resistance) as well as a cognitive function, for example, memory deficit.\(^ {7}\) It remains however, to be examined whether a lower efficiency of mitochondrial ATP production in maternal fructose exposed offspring, as observed in the present study, can be similarly linked with a change in cognitive function.

### Uncoupling Proteins and Mitochondrial Function

A decrease in P/O ratio is usually the effect of an increased proton leak through the inner mitochondrial membrane, for example, via an enhanced UCP activity.\(^ {24}\) To examine whether a change in the expression level of UCPs could be responsible for the decrease in P/O ratio in the fructose group, we measured mRNA levels of UCP1-5 and found a trend toward an increase in UCP5 mRNA, but not in the other UCP mRNA levels. Noteworthy, we found a strong inverse correlation between the P/O ratio and the UCP5 mRNA as well as protein levels.

A change in UCP5 expression in relation to brain mitochondrial respiration has been observed previously. Thus, a ketogenic diet induces an increase in brain mitochondrial respiration and phosphorylation efficiency.\(^ {25}\) As UCP5 has also been suggested to have a role in protection against oxidative stress and mitochondrial dysfunction,\(^ {26}\) the increase in UCP5 may also be a compensatory mechanism caused by the maternal fructose-induced changes in mitochondrial function. Coincidentally, another UCP, UCP1, has been shown to be regulated by epigenetic modification of its promoter,\(^ {30}\) and we speculate that the increased UCP5 mRNA levels observed in this study could be due to similar modifications of the UCP5 promoter caused by maternal fructose exposure. Currently, there are however no data regarding epigenetic regulation of UCP5 expression.

### Developmental Programming by Fructose

The results of the present study together with literature data support the hypothesis tested in the present study that a high-fructose intake during gestation can cause adverse developmental

---

**Figure 3.** Brain uncoupling protein 5 (UCP5) levels. (A) Brain UCP5 protein levels (mean ± s.e.m.) of 15-month-old Fischer F344 rats subjected to either a control diet or a fructose diet during gestation and lactation. (B) Pearson’s correlation between UCP5 protein levels and P/O ratios (see Table 3).

---

### DISCUSSION

In the present study, we examined the possible developmental programming effects of high-fructose exposure in early life upon mitochondrial function in the aging brain of 15-month-old offspring. We found that the high-fructose exposure resulted in significant differences in the function of brain mitochondria isolated from the aged offspring. Thus, mitochondria from the fructose group displayed an increased state 3 respiration rate, a decreased P/O ratio, and a strong inverse correlation between the P/O ratio and the UCP5 mRNA as well as UCP5 protein levels. In other words, we show for the first time that gestational fructose exposure has a pronounced developmental programming effect on brain mitochondrial function at old age in the offspring.

### Developmental Programming of Mitochondrial Function by Maternal Fructose Exposure

The brain mitochondria in the fructose group presented with an increased respiration and a lower energy conservation efficiency as reflected by a decreased P/O ratio as examined with malate

Journal of Cerebral Blood Flow & Metabolism (2014), 1205 – 1211
programming. Thus, fructose intake during gestation has been shown to cause changes in glucose metabolism,10,11,31 and lipid metabolism,10,32,33 as well as decreased fetal leptin signaling34 in the offspring. Several of the studies mentioned above also reported a fructose-induced decrease in birth weight,10,11 whereas others including the present study (Table 2) did not see this effect.31,33,34 The decrease in offspring body weight in adulthood seen in the present study (Figure 1) due to a high maternal fructose intake has been reported by others as well.11,31

In the present study, we found no difference in body fat percentage at 15 months but a lower snout-to-anus length suggesting that maternal fructose impairs development and/or the growth program of the offspring, perhaps involving changes in growth hormones during fetal life or early adulthood. One might also speculate that the observed effect of maternal fructose upon energy metabolism in offspring brain could be due to a disturbance of the hypothalamic pituitary adrenal axis, which is commonly associated with developmental programming.35

The pathophysiology of Fructose in a Metabolic Context
Fructose is thought to exhibit its long-term negative effects on metabolism by an increase in hepatic lipogenesis, primarily saturated fatty acids, causing dyslipidemia,36 an increase in low-grade inflammation,37 as well as increased oxidative stress.38 Pregnancy may exacerbate the adverse effects of fructose as several studies in rats have shown a faster and larger fructose induced increase in dam liver size during gestation compared with nonpregnant controls.31

Sufficient supply of essential fatty acids during gestation is important for normal fetal brain development39 and consuming an n-3 fatty acid deficient diet during gestation results in lasting changes in brain development in the offspring.40 One might speculate that the increase in nonessential saturated fatty acids in plasma caused by a maternal fructose diet might compete with transport of essential fatty acids across the placenta resulting in a fetal deficiency in n-3 fatty acids, and hence be one mechanism by which fructose affects the brain during gestation. Furthermore, maternal inflammation has been shown to cause adverse developmental programming of the offspring brain.41

CONCLUSIONS
The present study shows that a high-fructose intake during gestation and lactation results in developmental programming in the form of significant changes in the mitochondrial phenotype in the brain of aging offspring. The observed change in mitochondrial coupling between respiration and ATP formation most likely involves an increase in brain UCPS protein levels.
