Abstract. We have analyzed a large set of RXTE/PCA scanning and slewing observations performed between April 1996 and March 1999. We obtained the 3-20 keV spectrum of the cosmic X-ray background (CXB) by subtracting Earth-occulted observations from observations of the X-ray sky at high galactic latitude and far away from sources. The sky coverage is approximately $\sim 22.6 \times 10^3$ deg$^2$. The PCA spectrum of CXB in 3-20 keV energy band is adequately approximated by a single power law with photon index $\Gamma \sim 1.4$ and normalization at 1 keV $\sim 9.5$ phot/s/cm$^2$/keV/sr. Instrumental background uncertainty precludes accurate RXTE/PCA measurements of the spectrum of cosmic X-ray background at energies above 15 keV and therefore we can not detect the high energy cutoff observed by HEAO-1 A2 experiment. Deep observations of the 6 high latitude points used to model the PCA background provide a coarse measure of the spatial variation of the CXB. The CXB variations are consistent with a fixed spectral shape and variable normalization characterized by a fractional rms amplitude of $\sim 7\%$ on angular scales of $\sim 1$ square deg.

Key words. cosmology:observations – diffuse radiation – X-rays:general

1. Introduction

Many efforts over the last few decades have contributed to an understanding of the origin of the cosmic X-ray background (CXB) in the 2-10 keV band (e.g. Boldt 1987, Hasinger et al. 1991, Fabian & Barcons 1992, Mushotzky et al. 2000, Giacconi et al. 2002, Brandt et al. 2003). Most, if not all, of the CXB emission is explained by the superposition of point sources (AGNs) distributed over the Universe (see e.g. Rees 1980, Giacconi & Zamorani 1987, Setti & Woltjer 1989, Giacconi et al. 2002, Moretti et al. 2003).

Accurate measurements of the X-ray spectrum of the CXB were obtained from large solid angle measurements with collimated spectrometers aboard the HEAO-1 observatory. The HEAO-1 A2 experiment was designed specifically for this problem, with special care being taken to separate the signal from cosmic and instrumental backgrounds. The A2 proportional counter measurements from $\sim 3 - 60$ keV (Marshall et al. 1980) are extended to 1 MeV with the scintillators of the A4 experiment (Gruber 1992). Numerous other measurements have been made with imaging telescopes - EINSTEIN, ROSAT, ASCA, BeppoSAX, CHANDRA, and XMM (e.g. Wu et al. 1991, Gendreau et al. 1995, Chen et al. 1996, Miyaji et al. 1998, Vecchi et al. 1999, Mushotzky et al. 2000, Lamb et al. 2002). The HEAO-1 A2 measurements were made over a large solid angle with an instrument designed to ensure a precise instrumental background subtraction. The imaging experiments measured the CXB over a much smaller solid angle and could be subject to cosmic variance (see e.g. Barcons 1992, Barcons et al. 2000). The measurements made by X-ray telescopes all yield an absolute normalization significantly larger than that of HEAO-1 A2, a result difficult to explain by cosmic variance alone (e.g. Barcons et al. 2000).

The Proportional Counter Array (PCA) aboard Rossi X-ray Timing Explorer (RXTE) provides an opportunity to perform a new and independent measurement of the CXB spectrum based on nearly all sky data – the first such measurement since the HEAO-1 observations.

2. Data analysis and results

2.1. Data and software

The Rossi X-ray Timing Explorer (Bradt et al. 1993) carries three instruments including the X-ray spectrometer: the Proportional Counter Array (PCA). It consists of 5 independent Proportional Counter Units (PCUs) which are sensitive to photons in 2-60 keV energy range. For Crab-
Fig. 2. Map of the sky, reconstructed from slew observations of RXTE/PCA. For this map we used data from layer 1 of PCUs 0,1,2, 3-20 keV energy band. The grid is separated by 45° in $l$ and 30° in $b$. Open circles indicate the regions used to construct the PCA background model.

Fig. 1. Typical PCA background subtracted lightcurve during slew. The clear difference between the “sky” level and “Earth” level measures the CXB flux. The increase in countrate at the end of the lightcurve is caused by an X-ray source becoming un-occulted.

like spectra, 88% of the detected counts are below 10 keV. Due to its high effective area (~6400 cm$^2$ at 6-7 keV), relatively precise modeling of the instrumental background, and low deadtime, the PCA can reliably measure spectra for sources with flux greater than 1 mCrab, which is about the flux of the CXB integrated over the 1 degree beam of the PCA.

The RXTE is capable of fast slews (6 deg/min); typical operations include 1-2 slews per orbit. Although operations are planned to slew during the South Atlantic Anomaly or periods when targets are occulted to the greatest extent possible, a substantial amount of blank sky and dark earth occulted data is obtained. In addition, several Guest observer programs requested scanning observations over moderate areas of the sky. The slewing and scanning data can be used to construct maps of the sky with the ~1 deg resolution of the PCA collimator. (e.g. Revnivtsev & Sunyaev 2002). Scanning RXTE/PCA observations are very useful for the localization of newly discovered sources (Markwardt et al. 2000) and the study of extended structures on the X-ray sky, especially at relatively high energies (10-20 keV), where only limited amount of data exists (see e.g. Valinia & Marshall 1998, Revnivtsev 2003).

In our study we used RXTE/PCA data taken during reorientations (slews or scans) from April 16, 1996 through March 22, 1999. This time period was chosen to stay within a single high voltage epoch of PCA. The to-
The number of observations is approximately 17,600 with \( \sim 8.5 \) Msec of exposure. These data contain both clean-sky observations and Earth occulted observations. Clean-sky data provide the cosmic X-ray background signal, while Earth-occulted data provide information about the PCA instrument background.

The first attempts to model the PCA background used earth looking data as an estimate of the instrument background. No separation between dark and sunlit earth was made. The estimated CXB spectrum, using this background estimator, deviated from a power law with index \( \sim -1.4 \) at \( \sim 15 \text{keV} \), and also some soft component appeared, an effects that were attributed to reflection from the bright earth. Experience with BBXRT and ASCA (albeit at lower energies) suggests that the sunlit earth is more than an order of magnitude brighter than the dark earth. As we have taken care to include only dark earth data, and the statistically significant signal extends only to 15-20 keV, we are confident that the earth albedo is effectively zero for this experiment. At these low energies the Earth atmosphere, consisting of nitrogen and oxygen, is a very effective absorber, however at energies higher than 10-15 keV effect of reflection from the atmosphere plays an important role (see e.g. Pendleton et al. 1992) and should be taken into account.

Our analysis assumes that the dark Earth emits essentially zero flux in X-rays. In reality the emission of the dark Earth at higher photon energies is modified by the reflection of cosmic X-ray background and radiation from brightest X-ray sources. However below we would assume that the influence of this effect is small in the spectral band of our interest.

Data reduction was done using standard tools of LHEASOF 5.2 package. We analyzed data from PCA detectors PCU 0, 1 and 2, which have largest exposure times. Noisy parts of data were filtered out by applying the selection criteria ELECTRON_0,1,2 < 0.1. All results were corrected for the deadtime (http://legacy.gsfc.nasa.gov/docs/xte/recipes/pcadeadtime.html).

The effective field of view of the PCA is \( \Omega = 2.97 \cdot 10^{-4} \) sr. This value is derived by fitting scans over the Crab nebula to a model which convolves the response of a perfect hexagonal collimator (8 inches high with a 1/8 inch flat to flat opening) with a Gaussian (FWHM 6 arcmin, Jahoda et al. 1992). This model is appropriate for many independent and nearly co-aligned hexagonal collimators; the width of the Gaussian characterizes the average misalignment. While construction of the PCA collimators from corrugated sheets soldered together causes strong correlations between nearby collimator cells, the model works adequately to describe the ensemble of \( \sim 20,000 \) collimator cells per PCU.

To check the overall normalization (i.e. net area) of the PCA we analyzed the Crab monitoring observations obtained approximately every two weeks over the entire period during which CXB data was collected. We selected data from the same anodes as described above (layer 1, PCUs 0,1 and 2). With standard response matrix, produced by FTOOLS 5.2 package the photon index of the Crab spectrum in the 3-20 keV energy band was measured to be \( \Gamma = 2.09 \pm 0.01 \) with a normalization of \( N = 11.6 \pm 0.4 \) photon/s/cm²/keV (the value of neutral absorption column was fixed at \( N_H = 2 \cdot 10^{21} \) cm⁻²: the results in the PCA band are insensitive to this).

This fit predicts a Crab nebula flux of \( 2.66 \cdot 10^{-8} \) erg/s/cm² (2-10 keV) which is high compared to the "conventional" value. Zombeck (1990) reports the Crab spectrum as presented by Seward (1978) to be \( dN/dE = 10E^{-2.05} \) photon/s/cm²/keV, which gives a 2-10 keV flux of \( 2.39 \cdot 10^{-8} \) erg/s/cm². To our knowledge, more recent X-ray experiments have not measured this normalization directly, using instead this value as a standard candle. To put our measurements onto this scale, we correct our measured fluxes downward by a factor of 1.11; this is equivalent to increasing the estimated geometric area of the PCA. ¹ A multi-mission attempt to use type I X-ray bursts as standard candles reached a similar conclusion (Kuulkers et al. 2003) using an earlier version of the PCA response matrix.

Deviations between the modeled and measured Crab spectrum do not exceed \( \sim 1\% \). In all subsequent analysis we cite only statistical uncertainties unless otherwise noted. The quoted uncertainties are consistent with the statistical distributions of measured quantities.

We used the faint source ("L7_240") CM background model (http://heasarc.gsfc.nasa.gov/docs/xte/recipes/pcabackest.html). The background model includes by design both the cosmic and instrumental background, so the background subtracted rate for "blank sky" observations should be approximately zero. The background model is constructed from observations of six different blank sky points; the net background rate is slightly different for the six points due to spatial fluctuations of the CXB.

Combination of Earth-occulted observations with sky observations provides the spectrum of the CXB. The Earth is treated as a shutter in the front of the PCA. Fig. 1 illustrates this point. The "sky" rate is approximately zero; the decrement between sky and occulted data is just the CXB flux.

### 2.2. Map of the sky

In order to obtain the spectrum of the CXB, we need to avoid the contamination from bright galactic and extragalactic sources present in the data. For this purpose we have constructed the map of the sky using the same

¹ We (the GSFC co-authors) expect that the FTOOLS 5.3 package, anticipated for fall 2003 release, will increase the geometric area parameterization in the xpcarf tool, which will effectively reduce derived fluxes by this factor; given the good agreement in the spectral index between PCA and the other measurements, this boot-strap approach represents the best available calibration of the total area.
Standard2 data mode from which we collect the CXB spectrum.

The Standard2 data mode of the PCA is present in all observations, maintains the maximum useful energy resolution, separates data by anode, and provides 16 second time resolution. The background subtracted flux, measured by each PCU in 3-20 keV energy band during each 16 second time bin was ascribed to the point of the sky where the optical axis of the RXTE/PCA was pointed at the middle of the time bin. Angular resolution is limited by the size of the PCA beam (∼ 1° FWHM) and the movement of the optical axis during each 16 sec interval. The typical velocity of the RXTE optical axis on the sky – ∼ 1° FWHM results in the all-sky map limiting sensitivity of the obtained map to the data discussed here. These errors were added in quadrature to the statistical errors of the measured count rates. The net statistical and systematic uncertainties of measured CXB spectrum are shown by shaded area in Fig.2.

2.4. Cosmic variance

Measurements of the CXB are also affected by spatial fluctuations, or cosmic variance, over the sky (see e.g. Barcons et al. 2000). Our CXB spectrum, which averages over a huge solid angle, is expected to represent a well defined average, although the background model, which is based on observations of only 6 distinct deep exposure points, may be affected. Other instruments that measure the CXB spectrum over smaller solid angles may be directly affected by this variance.

The data used to create the background model also allows a limited measurement of the fluctuations on the scale of the PCA beam of ∼ 1°. We analyzed data from the 6 “background” points (marked with open circles in Fig.2).

After subtraction of the PCA instrument plus average sky background, the spectra of these sky areas are significantly different. The individual spectra can be described with a common power-law index but differing normalization. The fractional root-mean-square amplitude of this variation in normalization is 7 ± 1%. The dashed lines in Fig.3 show the ±1σ range of normalizations that would be measured over 1 square degree solid angles given this variation.

2.3. Spectrum of CXB

The unfolded spectrum of CXB is presented in Fig.3. The spectrum is well approximated by a single power law with a photon index Γ = 1.42 ± 0.02 and normalization $N = 9.8 \pm 0.3$ photon/cm²/keV/sr. If the slope is fixed at $\Gamma = 1.4$, the normalization is $N = 9.5 \pm 0.3$ photon/cm²/keV/sr. The observed flux of CXB in 3-10 keV energy band is $F_{3-10keV} = (5.17 \pm 0.05) \cdot 10^{-8}$ erg/cm²/sr. The normalizations and flux are reported after the downward correction of 1.11 described above.

The study of CXB emission with PCA is limited by the accuracy of the instrumental background subtraction above 10 keV. Unmodelled variation in the PCA background averages 0.027 ct/s/PCU in the 2-10 keV band and 0.013 ct/s/PCU in the 10-20 keV band (these figures are layer 1 only Markwardt et al. 2002 and thus relevant to the data discussed here).

The study of CXB emission with PCA is limited by the accuracy of the instrumental background subtraction above 10 keV. Unmodelled variation in the PCA background averages 0.027 ct/s/PCU in the 2-10 keV band and 0.013 ct/s/PCU in the 10-20 keV band (these figures are layer 1 only Markwardt et al. 2002 and thus relevant to the data discussed here).

These errors were added in quadrature to the statistical errors of the measured count rates. The net statistical and systematic uncertainties of measured CXB spectrum are shown by shaded area in Fig.3.

3. Conclusion

The large amount of slew data from the RXTE/PCA instrument allows us to study the spectrum and intensity...
of cosmic X-ray background averaged over a large solid angle.

After excluding areas around bright sources, Galactic plane region ($|b| < 20^\circ$) and regions of Large and Small Magellanic Clouds our data covers approximately $22.6 \times 10^3$ deg$^2$ of the sky. This data set measures, by definition, the average properties of the CXB.

The spectrum of the CXB in the 3–20 keV energy band obtained from RXTE/PCA slew data is well approximated by a power law in the form $dN(E)/dE = NE^{-\Gamma}$ with photon index $\Gamma = 1.42 \pm 0.02$ and normalization $N = 9.8 \pm 0.3$ phot/s/cm$^2$/keV/sr. Relatively large systematic uncertainties of the PCA instrumental background at $E > 15-20$ keV, and the decreasing ratio of CXB to instrument background did not allow us to study the spectrum above $\sim 20$ keV, and the high energy cut-off detected by HEAO-1 A2.

The slope of CXB spectrum obtained by RXTE/PCA agrees well with that obtained by other observatories. The normalization value is slightly higher, but marginally compatible with, HEAO-1 A2 ($\Gamma \approx 1.42$) obtained over a similarly large solid angle of the sky. The measurements of CXB normalization by different X-ray instruments give different variable values (Fig. 4, 5), however, the weighted average of the imaging measurements gives a value that is inconsistent with HEAO-1 A2 ($\Gamma \approx 1.42$) and consistent with ours.

Our measurement relies on a scaling of the absolute area of the PCA to match the canonical value of the flux from the Crab nebula; as many experiments have used the Crab as a standard candle and as our measurement of the spectral shape is in good agreement, this should add no more than a few per cent uncertainty. Our result is marginally compatible both with the result from the Xenon-filled, collimated proportional counters of HEAO-1 A2 and with the results from imaging instruments. However, observed subtle discrepancies between these measurements suggest that there are remaining systematic issues in the calibration of the effective area and/or solid angle in either the collimated or imaging experiments.
