**Abstract**

**Background:** Placental malaria (PM) is one major feature of malaria during pregnancy. A murine model of experimental PM using BALB/c mice infected with *Plasmodium berghei* ANKA was recently established, but there is need for additional PM models with different parasite/host combinations that allow to interrogate the involvement of specific host genetic factors in the placental inflammatory response to *Plasmodium* infection.

**Methods:** A mid-term infection protocol was used to test PM induction by three *P. berghei* parasite lines, derived from the K173, NK65 and ANKA strains of *P. berghei* that fail to induce experimental cerebral malaria (ECM) in the susceptible C57BL/6 mice. Parasitaemia course, pregnancy outcome and placenta pathology induced by the three parasite lines were compared.

**Results:** The three *P. berghei* lines were able to evoke severe PM pathology and poor pregnancy outcome features. The results indicate that parasite components required to induce PM are distinct from ECM. Nevertheless, infection with parasites of the ANKAΔpm4 line, which lack expression of plasmepsin 4, displayed milder disease phenotypes associated with a strong innate immune response as compared to infections with NK65 and K173 parasites.

**Conclusions:** Infection of pregnant C57BL/6 females with K173, NK65 and ANKAΔpm4 *P. berghei* parasites provide experimental systems to identify host molecular components involved in PM pathogenesis mechanisms.

**Keywords:** *Plasmodium berghei*, Placental malaria, Cerebral malaria, Placental pathology, TNF, TLR4, TLR2

**Background**

Organ pathology evoked by *Plasmodium* infections often correlates with accumulation of infected erythrocytes in specific organs leading to severe clinical manifestations as is the case of respiratory distress, cerebral malaria (CM) and severe placental malaria (PM) [1]. PM is one major feature of malaria during pregnancy and is usually associated with low birth weight due to intra-uterine growth retardation and/or preterm delivery ([2] and reviewed in [3]), stillbirths, maternal anaemia and mortality [4,5]. Placental malaria results from accumulation of parasitized erythrocytes that is associated with a prominent monocyctic inflammatory response that entails increased IFN-γ and TNF production and enhanced levels of monocyte/macrophage recruiting factors (MIP-1α and MIP-1β) [1,6]. Placental malaria pathology includes maternal-fetal barrier thickening, disorganization and destruction of placental tissue, proliferation of cytotrophoblastic cells and excessive perivillous fibrinoid deposits usually associated with focal syncytiotrophoblastic necrosis [7-10]. The severity of placental pathological manifestations is associated with a spectrum of severe pregnancy outcomes but the host cellular and molecular components that control the intensity of the inflammatory response are still not well-defined and are difficult to investigate in pregnant women.

An experimental system where *P. berghei* ANKA evokes a syndrome that resembles severe PM in women was established in a experimental cerebral malaria...
(ECM)-resistant mouse strain (BALB/c) allowing experimental investigation of PM pathogenesis in the mouse. Low foetal viability and increased maternal disease severity correlate with placenta pathology that, in this experimental model, is characterized by thickening of the placental barrier in the labyrinth zone and tissue damage, accumulation of monocyte/macrophages and enhanced expression of pro-inflammatory, apoptosis and oxidative stress factors [11-13]. The use of the *P. berghei* model of malaria for analysis of PM would benefit by development of additional experimental tools. Access to numerous (C57BL/6) mouse mutants would allow interrogating the involvement of host genetic factors in the placental inflammatory response to *Plasmodium* infection. Recently, the C57BL/6 mouse strain in combination with the rodent parasite *Plasmodium chabaudi* has been exploited to study pregnancy malaria pathogenesis with infection initiated early in gestation [14,15]. Here, different parasite lines derived from the *P. berghei* strains K173, NK65 and ANKA Δpm4 [16] that are not able to induce ECM in C57BL/6 mice, were used to establish additional placental malaria experimental models in this mouse strain. The results show that pregnant mice infected with the three lines develop PM indicating that *P. berghei* parasite factors that are responsible for inducing ECM in the C57BL/6 mouse are not required to induce placental pathology and poor pregnancy outcome in female mice infected during pregnancy. These experimental systems are valuable tools to study host and foetal genetic factors in the pathogenesis of placental response to *Plasmodium* infection.

**Methods**

**Mice and pregnancy monitoring**

Eight to twelve week-old C57BL/6 mice were obtained from the animal facility at Instituto Gulbenkian de Ciência. Mice were bred and maintained under specific-pathogen free (SPF) conditions. C57BL/6 females were transferred to a cage with one isogenic male (two females: one male) and removed after 48 hours. The day the females were removed was considered gestational day 1 (G1). Pregnancy was monitored every other day by weighing females. Successful fertilization was confirmed between G10 and G13 when animals had an average increase of 3 to 4 g in body weight. Abrupt weight loss after G13 was an indicator of unsuccessful pregnancy. Animal housing and all procedures were in accordance with national regulations on animal experimentation and welfare and approved by the Instituto Gulbenkian de Ciência Ethics Committee.

**Parasites and infection**

The following parasite lines were used in this study: i) A reporter parasite line of the K173 strain/isolate of *P. berghei* which expresses the reporter protein GFP-luciferase under the control of the schizont-specific ama-1 promoter. This mutant (line 1277c11) has been generated in the K173cl1 line [14]. The gfp-luciferase gene has been integrated into the c/d-ssu-rRNA unit by double cross-over integration without a drug selectable marker. Details of this line can be found in the RMgmDB database [17]; ii) A mutant of *P. berghei* ANKA which lacks expression of plasmepsin-4 (ANKAΔpm4; line 1092c14; RMgmDB-316) and expresses the reporter fusion protein GFP-luciferase under the control of the ama-1 promoter [16]; iii) a parasite line originally derived from the *P. berghei* isolate NK65 at New York University and kindly provided by Dr Maria Mota (Instituto de Medicina Molecular, Lisbon, Portugal). Infections in Figure 1 were performed by intraperitonial (i.p.) injection of 10⁶ infected erythrocytes (IE). Parasitized red blood cell preparations were obtained from one in vivo passage in C57BL/6 mice, when the percentage of infection reached approximately 10%. Pregnant mice were intravenously (i.v.) injected with 10⁶ infected erythrocytes. Infection with ANKAΔpm4 at G13 yielded very low parasite burden during pregnancy due to reduced multiplication rate of this parasite [16], but infection at G10 allowed significant parasite expansion within pregnancy time. Thus, infection was performed on

![Figure 1 Susceptibility to infection of C57BL/6 mice. (A) Time-course parasitaemia and (B) survival of *P. berghei* K173, NK65 and ANKAΔpm4 in C57BL/6 non-pregnant mice. Animals were infected i.p. with 10⁶ IE. Parasitaemia of DRAQ-5 labelled samples was followed by FACS. In (B) survival curves were compared using the Log-Rank (Mantel-Cox) test. Statistical significance results were p<0.01 when comparing K173 vs NK65 or ANKAΔpm4; p<0.05 when comparing NK65 to ANKAΔpm4.](image-url)
G10 (ANKAΔpm4 IE) or G13 (P. berghei K173 or NK65 IE). Parasitaemia was measured by flow cytometry [18] to detect infected erythrocytes stained with DRAQ5 (Biostatus Limited). The labelling of infected red blood cells with DRAQ5 is an adaptation of the manufacturer’s protocol for cell cycle analysis by flow cytometry. Briefly, a drop of blood was collected by tail pinching of infected mice into 400 μl of FACS Buffer (PBS 1x, 2% FBS, sodium azide 0.02%). DRAQ5 was added directly to the collected samples at a final concentration of 1μM. Samples were vortexed to allow an appropriate incorporation of DRAQ5 into the parasite DNA and immediately analysed. Uninfected red blood cells do not stain positive for DRAQ5 as they are devoid of DNA content. Parasitaemia was expressed as % of stained cells within the erythrocyte morphological gate. ECM development was monitored from day 5 post-infection (PI) as including one or more of the following neurological symptoms; head deviations, paralysis, ataxia and convulsions [19].

**Pregnancy outcome and foetal survival**

Infected pregnant mice were killed by CO2 narcosis and subjected to caesarian section on G18 (K173 or NK65 infection) or G19 (ANKAΔpm4 infection) and stillbirths, foetal weight, foetal survival at delivery and placental pathology were evaluated. Foetuses were extracted from their amniotic envelop and viability was immediately evaluated by reactive movement to touching with pliers. The lack of prompt movement indicated that the foetus had recently died. Reabsorptions were identified as small implants with no discernible foetus and placenta, corresponding to embryos that died before complete placentation. Viable and non-viable foetuses were weighed and counted. Non-viable (dead foetuses plus reabsorptions) foetuses were recorded as stillbirths. Viable foetuses were killed combining hypothermia and CO2 narcosis. In another set of experiments, infected pregnant mice were allowed to deliver in order to access their amniotic envelop and viability was immediately evaluated by reactive movement to touching with pliers. Survival curves were compared using the Log-Rank test (Mantel-Cox). Parasitaemia data were presented as mean ± SEM. Unpaired t test (Welch’s correction) was performed in comparison of each parasite line with the respective control group. Kruskal-Wallis non-

**RNA isolation and gene expression analysis**

Total RNA from individual placentas was obtained using an RNeasy Mini Kit (Qiagen), following the manufacturer’s instructions for animal tissues. One microgram of total RNA was converted to cDNA (Transcriptor First Strand cDNA Synthesis Kit, Roche) using random hexamer primers. Ccl2, Ccl3, Tlr2, Tlr4 and TNF expression was quantified using TaqMan Gene Expression Assays from ABI (Mm00441242_m1, Mm00441258_m1, Mm00442346_m1, Mm00445273_m1, Mm00443258_m1, respectively). For *P. berghei* ANKA quantification specific primers for Taqman were, Forward 5′-CCG ATC AAC GAG ATC TTA ACC T-3′; Reverse 5′- CGT CAA AAC CAA TCT CCC CCT AAC AA-3′ and Probe 5′- ACT CGC CGC TAA TTA G -3′ (FAM/MGB). The endogenous control Gapdh (Mouse GAPD Endogenous Control, ABI) was used in multiplex PCR with target genes. PCR reactions were performed with ABI Prism 7900HT system. For TaqMan assays, ΔCT was calculated by subtracting the cycle threshold (Ct) of the target gene from the GAPDH and relative quantification was obtained with normalization by GAPDH. Results were plotted as fold change over the respective non-infected controls.

**Statistical analysis**

Survival curves were compared using the Log-Rank test (Mantel-Cox). Parasitaemia data were presented as mean values ± SEM. Unpaired t test (Welch’s correction) was performed in comparison of each parasite line with the respective control group. Kruskal-Wallis non-
parametric test with Dunn’s post-test was used for comparisons between the three infected groups. Data were considered significant when $p<0.05$

**Results**

**Increased parasitaemia in pregnant mice**

As opposed to the canonical strain *P. berghei* ANKA, parasites of the NK65 isolate and of mutant ANKAΔpm4 have been previously described not to cause experimental cerebral malaria (ECM) in the C57BL/6 susceptible strain [13,15]. Similarly, the K173c11 line derived from the K173 isolate has lost the capacity to induce ECM [unpublished results, CJ and BF]. The course of infection by the three parasite variants in non-pregnant C57BL/6 females (Figure 1) showed that differently from wild-type *P. berghei* ANKA the three parasite lines do not induce the characteristic features of ECM. Nevertheless they induced hyperparasitaemia leading to a fatal outcome. *P. berghei* ANKAΔpm4 and NK65 exhibited slower growth kinetics when compared to the K173 line and corresponding delayed effects on the survival rate. To ascertain the effect of infection in pregnancy, mice were infected with K173 and NK65 at G13 when placenta vascularisation is established while infection with ANKAΔpm4 was performed at G10 due to reduced multiplication rate of this parasite [16]. Pregnant mice did not exhibit symptoms of ECM but showed higher parasitaemia across time as compared to non-pregnant females, reaching 20% at 5 to 9 days after infection (Figure 2) and indicating that parasites of the three lines show increased ability to cause hyperparasitaemia during pregnancy.

**Impaired pregnancy outcome**

The impact of infection in the pregnancy outcome was ascertained by the frequency of stillbirths *in utero* as well as foetal weight at G18 in pregnant females infected with NK65 and K173 or at G19 in ANKAΔpm4 infected mice. Intra-uterine foetal death was increased in pregnancies of NK65-infected mice (69% of the females had a high number of non-viable foetuses), in K173-infected mice (62%) and in ANKAΔpm4 infected pregnant (25%) when compared to non-infected controls (Figure 3A and Additional file 1). Viable and non-viable foetuses from NK65, ANKAΔpm4 and, to a lesser extent, from K173-infected mothers showed significantly reduced weight as compared to non-infected controls at the same gestational day (Figure 3B). Moreover, newborn viability at delivery was strikingly reduced (Table 1) as compared to non-infected pregnant females. In some instances NK65 infection provoked maternal death during pregnancy (Table 1). These results show that infection of C57BL/6 pregnant females with *P. berghei*-derived parasite lines that fail to induce ECM, recapitulate with different
degrees of severity the features of PM described in BALB/c mice infected with *P. berghei* ANKA [11,12] namely, intrauterine growth retardation and poor pregnancy outcome. Nevertheless, it was clear that infection with ANKAΔpm4 had milder effects on pregnancy outcome.

Placental pathology in C57BL/6 mice

Next, infected placentas were examined for pathological features typical of PM including syncytiotrophoblast thickening, tissue destruction, fibrin deposits, thrombi formation and reduction of maternal blood space [11]. HE-stained sections displayed variable degrees of localized trophoblast layer thickening, placental tissue disorganization (Figure 4 B-D) and associated necrosis foci in the labyrinth zone and thrombi (Figure 4E) as compared to non-infected placentas (Figure 4A). Morphometric analysis of the labyrinth zone revealed a significant reduction in the available area for maternal blood circulation in all infected groups when compared to non-infected controls but NK65-infected mothers showed the highest restriction in blood space area (Figure 4F). Thus, the severity of placental pathological alterations evoked by the three parasite lines is distinct which corroborated the observed differences in pregnancy outcome. Notwithstanding the observed differences in pregnancy outcome and placenta pathology, the infection with these three parasite lines did not result in significant differences in placental parasite burden (Figure 5). These results indicate that despite the observed differences in placental pathology and pregnancy outcome, the ability to accumulate in the placenta is not significantly different between the three *P. berghei* lines.

Differential patterns of placental inflammation

To investigate the differences in pregnancy outcome and placental immune response to infection elicited by the three *P. berghei* lines, gene expression of pro-inflammatory molecules and informative markers of innate and adaptive immune responses in infected placentas relative to non-infected controls were studied (Figure 6 and Additional file 2). Expression of Ccl2 (MCP-1), Ccl3 (MIP-1α), Tlr (Toll-like receptor) 2 and Tlr4 as well as Tnf was up-regulated in ANKAΔpm4-infected placentas as compared to the other parasite lines. Conversely, placentas of K173- and NK65-infected females exhibited less reactive inflammatory response. This strongly suggests that ANKAΔpm4 infection elicits an inflammatory response with a strong innate immunity component, which was not observed with parasites of the K173 and NK65 lines. Taken together, these results suggest that mechanisms involved in PM induction and progression might be different amongst different *P. berghei* lines and that these differences are not associated with the parasite burden in the placenta.

Discussion

Mouse models amenable to genetic dissection of host factors of PM pathogenesis were established by analysing the severity of maternal infection, pregnancy outcome, placental pathology and the expression of inflammatory factors following infection with three *P. berghei* lines that do not induce cerebral malaria in the C57BL/6 mouse. The results provide evidence that infection of pregnant females with

NI: non-infected; * Number of surviving mothers from a initial group of 5.
these *P. berghei* lines induces PM typical features, strongly suggesting that parasite factors determining cerebral malaria are not required to develop placental infection.

Nevertheless, the three parasite strains induced different degrees of placental pathology and impaired pregnancy outcome suggesting that parasite factors could underlie a spectrum of PM manifestations and distinct pathogenesis mechanisms. Thus, NK65 parasites induced the most severe syndrome comprising significantly lower foetal weight and decreased placental vascular area, higher percentage of nonviable foetuses per mother and lower number of live newborns. In addition, NK65 was the only parasite line causing maternal death before delivery (Table 1). Despite similar maternal parasitaemia in NK65 and K173-infected pregnant mice, the latter presented milder effects in placental pathology and in foetal weight loss. On the other hand, ANKAΔpm4 infection led to lower stillbirth incidence and increased newborn viability compared to the other strains. These observations support the notion that different *P. berghei* lines show distinct patterns of PM. In fact, an heterogeneous and wide range of clinical manifestations is also observed in women that have malaria during pregnancy, including increased levels of parasitaemia [20-23], increased number of abortions, preterm delivery, intrauterine growth retardation, low birth weight, maternal mortality [24-28] and structural placenta alterations such as trophoblast thickening and consequent vascular space reduction [8,29]. Thus, the different *P. berghei* lines represent a fine-tuning resource in constructing experimental systems to study different aspects of pregnancy associated malaria pathogenesis.

It is widely accepted that accumulation of IE is a key event in the pathogenesis of severe disease as is the case

---

**Figure 4 Placental histology of labyrinth zone and morphometric analysis.** Representative photomicrograph of H&E stained placental sections of non-infected (NI) (A), K173 (B), NK65 (C) and ANKAΔpm4 infected pregnant mice (D). (E) Histological sections show necrotic foci (arrow) and thrombi (arrowhead) in placenta infected with ANKAΔpm4 (upper picture) and K173 (lower picture) parasites. (F) Relative quantification of vascular space using an automated morphometric procedure in H&E stained sections evaluated in placental sections. Mice were infected i.v. with 10⁶ *P. berghei* K173 or NK65 IE (G13) or ANKAΔpm4 IE (G10); placenta were excised on G18 (K173 and NK65) or G19 (ANKAΔpm4). of respiratory distress, CM and severe PM [1]. The experiments here presented confirmed that PM development was associated with parasite accumulation in the placenta. Nevertheless, the parasite burden in the placenta was not a major determinant of PM severity as the distinct pathology patterns observed in mice infected with NK65, K173 and ANKAΔpm4 did not correlate with differences in placenta parasite accumulation. In particular, infection with the ANKAΔpm4 line showed a lower impact on foetal viability despite a similar parasite burden in the placenta. An earlier report shows that, ANKAΔpm4 parasites failed to induce disease in an ECM model but the resistance phenotype was correlated with lower parasite accumulation in the brain compared to wild-type *P. berghei* ANKA parasites. This virulence-attenuated effect was also observed in ECM-resistant mouse strains where self-resolving infection was associated to antibody-mediated response [16]. Nevertheless, this protective effect was not observed in ANKAΔpm4-infected pregnant mice although foetal viability was increased and correlated with a strong innate immune response. This raises the possibility that the vigorous local innate response in ANKAΔpm4 infected placentas deterred the progression of placental tissue disorganization at least for a short period warranting an improved pregnancy outcome. Although expression of pro-inflammatory markers was less stimulated in K173 and NK65-infected placentas at G18 it is not ruled out the possibility that gene expression differences are not exclusively parasite line-related but could also be influenced by differences in parasite kinetics as parasite expansion in pregnant ANKAΔpm4 mice was somewhat slower as compared to K173 and NK65. Thus, the observed differences in immune responses might also be influenced by the longer exposure of the maternal immune system to ANKAΔpm4 (G10 to G19) as compared to K173 and NK65 parasite lines (G13 to G18). Nevertheless, the PM protracting effects observed in ANKAΔpm4 infection offer now interesting research perspectives. This experimental model can be used to (1) discriminate between the effects exerted by foetal- and maternal-derived inflammatory factors in PM pathogenesis and (2) to ascertain whether innate immune responses can be used to provide effective foetal protection in PM.

**Conclusions**

The experiments here presented made use of three different *P. berghei* lines and show that parasite components that induce pathology during pregnancy are
distinct from those that induce experimental cerebral malaria. In addition, the data indicate that PM pathology in ANKAAAmp4 infected mice is associated with an inflammatory response with strong innate immune component, which was not observed in K173- and NK65-infected pregnant mice. The characterization of different experimental systems of PM in the C57BL/6 mouse will allow interrogation of genetically modified mice to ascertain the role of host molecules in PM pathogenesis and to dissect foetal and maternal contributions in placental pathology.

Additional files

**Additional file 1: Table.** Infection during pregnancy increases the percentage of stillbirths.

**Additional file 2: Figure.** Gene expression of inflammatory factors in non-infected placentas. Placentas from healthy pregnant females were collected at G18 or G19 and RNA expression of Ccl2, Ccl3, Tlr2, Tlr4 and Tnfa genes were evaluated by qReal Time PCR. Relative quantification (RQ) was obtained with normalization by GAPDH. *p<0.05.
