Abstract. The triple-alpha process, whereby evolved stars create carbon and oxygen, is believed to be fine-tuned to a high degree. Such fine-tuning is suggested by the unusually strong temperature dependence of the triple-alpha reaction rate at stellar temperatures. This sensitivity is due to the resonant character of the triple-alpha process, which proceeds through the so-called “Hoyle state” of $^{12}\text{C}$ with spin-parity $0^+$. The question of fine-tuning can be studied within the \textit{ab initio} framework of nuclear lattice effective field theory, which makes it possible to relate \textit{ad hoc} changes in the energy of the Hoyle state to changes in the fundamental parameters of the nuclear Hamiltonian, which are the light quark mass $m_q$ and the electromagnetic fine-structure constant. Here, we update the effective field theory calculation of the sensitivity of the triple-alpha process to small changes in the fundamental parameters. In particular, we consider recent high-precision lattice QCD calculations of the nucleon axial coupling $g_A$, as well as new and more comprehensive results from stellar simulations of the production of carbon and oxygen. While the updated stellar simulations allow for much larger \textit{ad hoc} shifts in the Hoyle state energy than previously thought, recent lattice QCD results for the nucleon S-wave singlet and triplet scattering lengths now disfavor the scenario of no fine-tuning in the light quark mass $m_q$.

1 Introduction

The production of carbon and heavier elements in stars is complicated by the instability of the $^8\text{Be}$ nucleus. The way this bottleneck is circumvented in nature is by means of the triple-alpha process, where the production rate of $^{12}\text{C}$ is strongly enhanced by a fortuitously placed $0^+$ resonance, known as the Hoyle state.\textsuperscript{1} As small \textit{ad hoc} changes in the excitation energy of the Hoyle state relative to the triple-alpha threshold can lead to large changes in the relative abundance of carbon and oxygen, the question arises whether the universe should be regarded as fine-tuned with respect to the likelihood of carbon-oxygen based life to arise, for a recent review on fine-tunings see \textsuperscript{2}. The physics of the triple-alpha process has recently been studied using nuclear lattice effective field theory (NLEFT). The ground state energies of $^4\text{He}$, $^8\text{Be}$ and $^{12}\text{C}$, and of the energy of the Hoyle state in $^{12}\text{C}$, were all found to be strongly correlated with respect to small changes in the fundamental constants of nature, an effect of the clustering of alpha particles in the respective nuclei. We review here how the sensitivity of the triple-alpha reaction rate with respect to small changes in the light quark mass and the electromagnetic fine-structure constant is treated in the effective field theory (EFT) framework. The main source of uncertainty is due to the short-range part of the nucleon-nucleon interaction, and we discuss recent progress in narrowing down this uncertainty using updated theoretical knowledge of the quark mass dependence of the two-nucleon S-wave scattering parameters, including the results of recent lattice QCD work. We also contrast this theoretical treatment with recent high-precision calculations of stellar nucleosynthesis, which find that the allowable range of Hoyle state energies is larger than previously thought \textsuperscript{3}.

This paper is structured as follows. In Sec.\textsuperscript{2} we update the pion (quark) mass dependence of the nuclear Hamiltonian, which is central for the following discussion. In Sec.\textsuperscript{3} we review the current status of stellar nucleosynthesis calculations, with focus on the resulting abundances of carbon and oxygen under \textit{ad hoc} shifts in the Hoyle state resonance. In particular, we pay attention to recent new results in this field. In Sec.\textsuperscript{4} we revisit the theoretical status of EFT calculations of the sensitivity of the Hoyle state energy to small changes in the light quark mass $m_q$.\textsuperscript{4}
and the electromagnetic fine-structure constant $\alpha_{\text{em}}$. Finally, in Sec. 5 we discuss how the EFT treatment of the triple-alpha process could be improved with regards to recent progress in the nuclear lattice EFT description of the nuclear forces.

2 Quark mass dependence of the nuclear Hamiltonian

The ground-state energies and spectra of light and medium-mass nuclei can be calculated to a good precision in the framework of NLEFT, as described in detail in the monograph [4]. Variations of the fundamental parameters like the average light quark mass or the electromagnetic fine-structure constant can also be investigated within this approach. In what follows, we update our knowledge of the quark mass dependence of the nuclear Hamiltonian, which is central to the study of fine-tunings in the triple-alpha process. Note that to high accuracy the Gell-Mann-Oakes-Renner relation

$$M_{\pi}^2 \sim m_q$$

is central to the study of fine-tunings in the triple-alpha process. In particular, consistent values of $g_A$ with minimal model dependence were obtained for a range of polynomial and chiral perturbation theory (ChPT) extrapolations in $M_{\pi}$. In order to make use of the analysis of Ref. [10], we define

$$\frac{\partial g_A}{\partial M_{\pi}} = \frac{\partial g_A}{\partial M_s} \frac{\partial M_s}{\partial M_{\pi}},$$

(4)

where

$$M_s \equiv \frac{M_{\pi}}{4\pi F_{\pi}},$$

(5)

and

$$\frac{\partial M_s}{\partial M_{\pi}} = \frac{1}{4\pi F_{\pi}} \left(1 - \frac{M_{\pi}}{F_{\pi}} \frac{\partial F_{\pi}}{\partial M_{\pi}}\right),$$

(6)

in terms of which

$$g_A = 1.273(19), \quad \frac{\partial g_A}{\partial M_{\pi} |_{M_{\pi}^0}} = -0.08(24),$$

(7)

were obtained from an extrapolation using the complete NNLO chiral expression, with and without inclusion of the N3LO contact terms [11]. It should be noted that unlike the determination of $g_A$ itself, the value of $\partial g_A/\partial M_{\pi}$ does depend significantly on the choice of extrapolation of the lattice QCD data. For instance, significantly larger values can be obtained by means of linear or quadratic extrapolations in $M_{\pi}$. However, we shall here rely on the chiral NNLO result [7], in particular as it was found to show good convergence of the chiral expansion [10].

The dependence of $F_{\pi}$ on $M_{\pi}$ was not yet obtained in Ref. [10]. We recall that Ref. [12] provided

$$\frac{\partial F_{\pi}}{\partial M_{\pi} |_{M_{\pi}^0}} = 0.066(16),$$

(8)

which was used in Ref. [6]. This should be compared with the sub-leading order ChPT result

$$\frac{\partial F_{\pi}}{\partial M_{\pi} |_{M_{\pi}^0}} = \frac{M_{\pi}}{8\pi^2 F_{\pi}} \ell_4,$$

(9)

where $F \simeq 86.2$ MeV denotes $F_{\pi}$ in the chiral limit, and $\ell_4 = 4.3(3)$ from the review [13]. We note that Eq. (9) gives a number comparable with (though slightly larger than) Eq. (5). These values are also consistent with the most recent FLAG lattice QCD determination [14].

Using the isospin-averaged pion mass $M_{\pi} = 138.03$ MeV and $F_{\pi} = 92.1$ MeV, we find

$$\frac{\partial M_{\pi}}{\partial M_{\pi} |_{M_{\pi}^0}} = 0.078(2) \text{ l.u.},$$

(10)

from Eq. (6), for an inverse spatial lattice spacing of $a^{-1} \equiv 100$ MeV. So far, from Eq. (3) and (8), we have

$$x_2 = -0.050(12) \text{ l.u.} + \frac{1}{2 F_{\pi}} \left(\frac{\partial g_A}{\partial M_{\pi} |_{M_{\pi}^0}}\right)_{M_{\pi}^0},$$

(11)
where we can now use the chiral lattice QCD extrapolations (7) together with Eq. (10). This gives
\[
\frac{\partial g_A}{\partial M_{\pi}} \bigg|_{M_{\pi}^{ph}} = -0.006(19) \text{ l.u.}, \tag{12}
\]
such that we finally obtain
\[
x_2 = -0.053(16) \text{ l.u.}, \tag{13}
\]
from Eq. (3), which is compatible with the range \( x_2 = -0.056 \ldots 0.008 \text{ l.u.} \) used in Ref. [6]. However, in contrast to the earlier determination of \( x_2 \), we can now pin it down with a definite sign up to \( \simeq 3.3 \sigma \).

Having fixed the hadronic input parameters, we now consider the leading order four-nucleon contact interactions that can be mapped on the derivatives of the inverse singlet and triplet neutron-proton scattering lengths,
\[
\tilde{A}_{s,t} = \frac{\partial a_{s,t}^{-1}}{\partial M_{\pi}} \bigg|_{M_{\pi}^{ph}}. \tag{14}
\]

Earlier, modelling based on resonance saturation [15] was used to get a handle on these quantities, as discussed in detail in Ref. [12]. Here, we attempt to fix \( A_{s,t} \) from available lattice QCD data, which should be the method of choice. Before doing so, some words of caution are in order. The situation with lattice QCD simulations in the nucleon-nucleon (NN) sector is at present highly controversial. Fully dynamical simulations at unphysically heavy pion masses, carried out by the NPLQCD Collaboration and Yamazaki et al. and based on the standard approach to extract the ground state energy by fitting plateaus of the correlation functions find more attraction in both the \( ^1S_0 \) and \( ^3S_1 \) channels at heavy pion masses than for physical pion masses, see [16,17,18,19,20]. These results contradict the findings of the HAL QCD Collaboration using a (scheme-dependent) potential at the intermediate stage of extracting NN observables. This group finds no bound states in both S-wave channels for pion masses ranging from 469 to 1171 MeV [21]. The HAL QCD Collaboration has already carried out simulations at the physical point, but the results for the nonstrange channels have, as far as we know, not been released yet. The HAL QCD Collaboration has criticized the direct method by pointing out the danger of observing fake plateaus [22,23], see, however, the response of the NPLQCD Collaboration in Ref. [24]. The HAL QCD approach has also been criticized e.g. in Refs. [25,26]. The weakest point of this method seems to be its reliance on the derivative expansion, whose convergence is not clear a priori. Interestingly, the recent lattice QCD study in the strangeness \( S = -2 \) two-baryon sector by the CERN-Mainz group [27] using a superior distillation method finds for \( M_\pi = 960 \text{ MeV} \) the H-dibaryon energy perfectly consistent with HAL QCD, but in a strong disagreement with the NPLQCD result.

Recently, in Ref. [28] the use of low-energy theorems (LETs) to reconstruct the energy dependence of the NN scattering amplitude in a large kinematical domain from a single observable (e.g. binding energy, scattering length, effective range) at a given fixed value of the pion mass was proposed. The method relies on the dominance of the one-pion exchange (OPE) at large distances, which governs the near-threshold energy dependence of the scattering amplitude. At the physical point, LETs are known to work accurately in the \( ^3S_1 \) channel in line with the strong tensor interaction induced by the OPE, while less accurately in the \( ^1S_0 \) partial wave, where the OPE potential is very weak [29]. Notice that this approach employs the lattice QCD results to determine the strength of the OPE potential at unphysical values of \( M_\pi \) and does not rely on the chiral expansion. At heavy pion masses \( M_\pi \sim M_\rho \), the LETs lose their predictive power, and the approach becomes equivalent to the effective range expansion. In [28], the LETs were used to test the linear interpolation of \( M_\pi r \) as function of \( M_\pi \) between \( M_\rho^{ph} \) and \( M_\rho \simeq 800 \text{ MeV} \) conjectured by the NPLQCD Collaboration [19]. This study was restricted to the \( ^3S_1 \) channel. The assumed linear interpolation was indeed found to be consistent with the available lattice QCD results for the deuteron binding energy obtained using the plateau method, see Fig. 6 of Ref. [28]. In [30] the LETs were applied to test the consistency between the bound state energies and phase shifts obtained using the Lüscher method by the NPLQCD Collaboration at \( M_\pi = 450 \text{ MeV} \) [18] in both the \( ^1S_0 \) and \( ^3S_1 \) channels. It was found that the NPLQCD phase shifts are inconsistent with their own results for the deuteron and dineutron energies. The inconsistency was later emphasized by the HAL QCD Collaboration using the effective range expansion [22,23].

With these drawbacks and inconsistencies in mind, we nevertheless go forward and analyze the available lattice-QCD results for the deuteron and dineutron binding energy of Refs. [16,17,18,19,20], which seem to be mutually consistent, in order to extract the quantities \( A_s \) and \( A_t \). The best way to extract \( A_{s,t} \) is to use the LETs to compute the inverse scattering lengths from the binding energies at the corresponding values of \( M_\pi \), and to perform a subsequent interpolation. In table 1 we collect the binding energies of the deuteron and dineutron states from the calculations of Refs. [17,18,19,20] and the resulting values of the inverse scattering lengths. In addition to these results, we also include the direct NPLQCD determination of the scattering lengths at \( M_\pi \simeq 800 \text{ MeV} \) from Ref. [19]
\[
a_t^{-1} = 0.549(59) \text{ fm}^{-1} , \quad a_s^{-1} = 0.429(54) \text{ fm}^{-1}. \tag{15}
\]
To perform the interpolation between these five points and the experimental values of the inverse scattering lengths, see Fig. 1 we use a simple quadratic ansatz
\[
a_{s,t}^{-1}(M_\pi) = (a_{s,t}^{ph})^{-1} + a(M_\pi - M_\rho^{ph}) + b(M_\pi - M_\rho^{ph})^2, \tag{16}
\]
where the coefficients \( a, b \) are determined from a least square fit to the available values of \( a_{s,t}^{-1} \) at heavier-than-physical pion masses. The results of the fits are shown by the solid (black) lines in Fig. 1. With \( \chi^2/\text{d.o.f.} = 4.3 \) and 2.4 in the singlet and triplet channels, respectively, the quality of the fit is not really good. Using a third-degree polynomial leads to the results shown by the dotted
Table 1. Available lattice QCD results for the deuteron and dineutron binding energies obtained from the plateau method along with the resulting values of the inverse scattering lengths calculated from the LETs at NLO. The uncertainties in the energies are taken from the corresponding papers. The first error of $a_{s,t}^{-1}$ reflects the uncertainty of the lattice results for the binding energies used as input (for $M_\pi = 300, 390$ and $510$ MeV, the different lattice errors for the binding energies have been added in quadrature), while the second one corresponds to the uncertainty of the LETs estimated as explained in Ref. [20].

| $M_\pi$ [MeV] | $B_0$ [MeV] | $a_{s,t}^{-1}$ [fm$^{-1}$] |
|---------------|-------------|--------------------------|
| $300$         | 14.5(0.7)$^{(+1.4)}_{-0.8}$ | $0.422^{(0.024)}_{-0.011}(^{+0.008})$ |
| $390$         | 11(05)(12)  | $0.400^{(0.019)}_{-0.011}(^{+0.018})$ |
| $450$         | $14.4^{(+3.2)}_{-2.6}$     | $0.448^{(0.039)}_{-0.092}(^{+0.042})$ |
| $510$         | $11.5^{(+1.1)}_{-0.6}$      | $0.419^{(0.015)}_{-0.016}(^{+0.077})$ |

The $^7$S$_1$ channel

| $B_{nn}$ [MeV] | $a_{s,t}^{-1}$ [fm$^{-1}$] |
|---------------|--------------------------|
| $8.5(0.7)^{(+1.6)}_{-0.9}$ | $0.335^{(0.023)}_{-0.013}(^{+0.009})$ |
| $7.1(5.2)(7.3)$ | $0.324^{(0.024)}_{-0.024}(^{+0.019})$ |
| $12.5^{(+3.6)}_{-5.6}$ | $0.324^{(0.020)}_{-0.004}(^{+0.055})$ |
| $7.4(1.3)(0.6)$ | $0.337^{(0.021)}_{-0.025}(^{+0.183})$ |

Fig. 1. Pion mass dependence of the inverse scattering lengths $a_{s,t}^{-1}$ as predicted by lattice-QCD calculations of Refs. [17-19]. Black squares show the experimental values at the physical point. Black solid and blue dashed lines are the quadratic and cubic interpolations.

The original estimation in Refs. [6,12]:

$A_s = 0.29_{-0.23}^{+0.25}$, $A_t = -0.18_{-0.10}^{+0.10}$.

LO chiral EFT of Ref. [31]:

$A_s = 0.50_{-0.23}^{+0.3}$, $A_t = 0.12_{-0.23}^{+0.08}$.

Interpolation of lattice QCD data of Refs. [16,17,18,19,20]:

$A_s = 0.54_{-0.23}^{+0.24}$, $A_t = 0.33_{-0.23}^{+0.16}$.

The LO chiral EFT result in Eq. (18) corresponds to an renormalizable expression for the scattering amplitude with the static one-pion exchange, and the uncertainty is estimated from the cutoff variation from $\Lambda = 600$ MeV to infinity. The positive sign of $A_t$ in Eq. (19) is consistent with a stronger attraction in the deuteron channel at heavy $M_\pi$, HAL QCD results would presumably yield a negative value of $A_t$. In what follows, we will use the values collected in Eq. (19).

3 The Hoyle state in stellar nucleosynthesis

The stellar synthesis of elements heavier than $^4$He is complicated by the fact that no stable nucleus exists for $A = 8$, at least for the physical values of the fundamental constants. In the absence of stable $^8$Be nuclei, helium fusion instead takes place through the triple-alpha reaction $3(^4\text{He}) \rightarrow ^{12}\text{C} + \gamma$, which requires a number of intermediate steps. The first step is $^4\text{He} + ^4\text{He} \leftrightarrow ^8\text{Be}$, whereby a transient equilibrium population of $^8$Be is maintained in the stellar core. It should be noted that the unstable $^8$Be resonance decays back into two alpha particles with a half-life of $\sim 10^{-16}$ s. The reaction rate for the formation of $^8$Be is controlled by the energy difference

$$\Delta E_b \equiv E_b - 2E_4,$$

(blue lines), but the $\chi^2/N_{\text{DOF}}$ well below 1 indicates overfitting. The large values of $\chi^2/N_{\text{DOF}}$ with a quadratic fit are likely due to underestimated error bars of lattice-QCD results, especially the ones from [17] at $M_\pi = 300$ MeV. In any case, we obtain $\bar{A}_s = 0.54$ and $\bar{A}_t = 0.33$ based on the quadratic interpolation. The cubic extrapolation yields $\bar{A}_s = 0.78$ and $\bar{A}_t = 0.49$, and we take the difference as an estimation of the uncertainty in $\bar{A}_{s,\ell}$. To summarize, the various available determinations of $\bar{A}_{s,\ell}$ are:

$$\bar{A}_s = 0.29_{-0.23}^{+0.25}, \quad \bar{A}_t = -0.18_{-0.10}^{+0.10}.$$
where $E_4$ and $E_8$ denote the ground states of $^4$He and $^8$Be, respectively. Though $^8$Be is short-lived, a sufficiently large transient $^8$Be population in stellar cores is formed to allow for the second step $^8$Be + $^4$He $\to$ $^{12}$C in the triple-alpha process.

In stellar cores composed primarily of helium, the non-resonant reaction proceeds too slowly to explain the observed abundances of carbon and oxygen in the universe. However, as the $^{12}$C nucleus possesses an excited $^{12}$C$(0_{1}^{+})$ state (known as the Hoyle state) with an empirical excitation energy of 7.6444 MeV, the reaction can also proceed in a resonant manner, which greatly enhances the triple-alpha reaction rate. We define

$$
\Delta E_h \equiv E_{12}^{\ast} - E_8 - E_4,
$$

which controls the reaction rate for the second step $^8$Be + $^4$He $\leftrightarrow ^{12}$C$(0_{1}^{+})$, where $E_{12}^{\ast}$ is the (total) energy of the Hoyle state resonance. The energy scale $E_R$ which controls the resonant triple-alpha reaction is then

$$
E_R \equiv \Delta E_b + \Delta E_h = E_{12}^{\ast} - 3E_4,
$$

which is empirically known (in our universe) to be $E_R^{\text{th}} = 379.47(18)$ keV. Note that this is much smaller than the binding energies of the nuclei participating in the triple-alpha reaction, which are $\simeq 28$ MeV for $^4$He and $\simeq 92$ MeV for $^{12}$C.

For a stellar plasma at temperature $T$, the reaction rate $r_{3\alpha}$ for fusion of three alpha particles via the ground state of $^8$Be and the Hoyle state of $^{12}$C is

$$
r_{3\alpha} = 3.17 N_a^{\frac{3}{2}} \left( \frac{2\pi h^2}{|E_4| k_B T} \right)^3 \frac{\Gamma_{\gamma}}{\hbar} \exp \left( -\frac{E_R^{\gamma}}{k_B T} \right),
$$

where $N_a$ is the number density of alpha particles, and $k_B$ is the Boltzmann constant. It should be noted how the exponential dependence on $E_R$ and $T^{-1}$ arises, as the observation that the rate of stellar carbon production is exponentially sensitive to $E_R$ is central to the anthropic picture of the triple-alpha process, for discussions on this issue see [32-33]. For non-resonant reactions, the corresponding factor is given by the convolution of Coulomb barrier penetration with a thermal distribution of particle velocities, which gives a $\sim T^{-1/3}$ dependence on temperature. For resonant reactions a fixed energy is singled out, in this case given by Eq. (22), which leads to the exponential dependence of Eq. (23). It should be noted that $E_R$ is clearly the dominant control parameter of the triple-alpha process, in comparison with the linear dependence on the radiative width $\Gamma_{\gamma} \approx 0.0037$ eV of the Hoyle state. Still, $\Gamma_{\gamma}$ should be sufficiently large to allow for the radiative decay of the Hoyle state to be competitive with fragmentation into $^8$Be and $^4$He. The radiative decay proceeds either through $^{12}$C$(0_{1}^{+})$ $\to$ $^{12}$C$(0_{1}^{+}) + \gamma$, or $^{12}$C$(0_{2}^{+})$ $\to$ $^{12}$C$(2_{1}^{+}) + \gamma$, after which the $^{12}$C$(2_{1}^{+})$ decays to the ground state $^{12}$C$(0_{1}^{+})$ by emission of a second photon. In practice, this two-step $E2$ process is more efficient than the direct $M0$ decay, which is highly suppressed. Interestingly, the channel $^{12}$C$(0_{2}^{+})$ $\to$ $^{12}$C$(2_{1}^{+}) + \gamma$ is strongly enhanced compared to the single-particle Weisskopf rate (often referred to as “strongly collective behavior”), which is correctly predicted by recent lattice EFT calculations. We define

$$
\delta E_R \equiv E_R - E_R^{\text{th}},
$$

when the energy of the Hoyle state is shifted from its physical value. Clearly, for $\delta E_R > 0$ (the Hoyle state energy is increased), the rate of carbon production (at constant stellar temperature $T$) is decreased. In order to generate sufficient energy to counteract gravitation, the stellar core must increase $T$ in order to compensate for the reduction in $r_{3\alpha}$. It should be noted that the production of $^{12}$C via the triple-alpha reaction competes with the destruction of $^{12}$C by the formation of $^{16}$O through $^{12}$C+$^4$He $\to ^{16}$O+$\gamma$, such that even a small change in $T$ could lead to a C/O abundance which is very different from that observed. However, the $^{16}$O nucleus has a state with excitation energy 7.1187 MeV, which is below the threshold energy of the $^{12}$C+$^4$He system, which is 7.1616 MeV above the ground state of $^{16}$O. Hence, the formation of $^{16}$O is a non-resonant process, which nevertheless depends sensitively on $T$ because of the sizeable Coulomb barrier.

On a phenomenological level, a variation of $E_R$ thus leads to a change in the relative importance of the competitive processes by which $^{12}$C is produced, and destroyed by further processing into $^{16}$O (and heavier alpha nuclei). Hence, for a sufficiently large positive $\delta E_R$, a regime is encountered in which little $^{12}$C and $^{16}$O remains after stellar nucleosynthesis, with most material having been processed into $^{24}$Mg and $^{28}$Si. Conversely, for negative $\delta E_R$, stellar core temperatures during helium burning are substantially lower, leading to end products with plentiful $^{12}$C but relatively little $^{16}$O. However, the latter point turns out to be sensitive to the initial stellar metallicity. Also, when the Hoyle state energy is lowered ($\delta E_R < 0$), one should also consider the sensitivity

$$
\Xi_T \equiv \frac{T}{r_{3\alpha}} \frac{dr_{3\alpha}}{dT} = -3 + \frac{E_R}{k_B T},
$$

where the stability of the star requires that the triple-alpha reaction rate (and hence the energy production) increase as $T$ increases, such that $\Xi_T > 0$. Hence, $E_R$ should satisfy

$$
E_R > 3k_B T,
$$

which places a lower bound on the permissible values of the Hoyle state energy. However, as stellar cores have roughly $k_B T \approx 10$ keV during helium burning, this bound is an order to magnitude smaller than the observed value of $E_R \approx 380$ keV.

Recently, comprehensive simulations of stellar nucleosynthesis in massive stars that eventually explode as supernovae have become available [3]. These studies follow stars ranging from 15 to 40 solar masses up to the stage where a degenerate iron core is formed. The yields of various isotopes are then weighted according to the stellar mass distribution function, taken to be $dN/dM/\odot \propto M^{-2.3}$ (for the range of stellar masses $M/\odot$ considered), which accounts for the relative scarcity of heavier stars. For the
stellar metallicity, Ref. [3] considered two cases. Firstly, the low-metallicity simulations used $Z = 10^{-4}$, which is representative of the currently known stars with the lowest observed metallicity. Secondly, the case of $Z = Z_{\odot}$ was studied, where $Z_{\odot} = 0.02$ denotes the observed solar metallicity. The main effect of $Z$ is to alter the relative importance of the $p-p$ chain and the CNO cycle, such that stars can enter the helium burning phase with different configurations.

We are now in a position to summarize the findings of Ref. [3] for the range in $\delta E_R$, for which the final abundances of $^{12}$C and $^{16}$O exceed their initial values. These can be expressed as

$$\delta E_R^{(-)} \leq \delta E_R \leq \delta E_R^{(+)}$$

where the boundaries for each nucleus depend on the chosen initial stellar metallicity. For $Z = 10^{-4}$ (low metallicity), the ranges compatible with carbon-oxygen based life are

$$^{12}\text{C}(Z = 10^{-4}) : -300 \text{ keV} \leq \delta E_R \leq 500 \text{ keV},$$

and

$$^{16}\text{O}(Z = 10^{-4}) : -300 \text{ keV} \leq \delta E_R \leq 300 \text{ keV},$$

where for negative $\delta E_R$, sufficient $^{12}$C and $^{16}$O were produced for all values of the Hoyle state energy compatible with the constraint [29]. For $Z = 0.02$ (solar metallicity), the corresponding ranges were found to be significantly narrower. Specifically,

$$^{12}\text{C}(Z = 0.02) : -300 \text{ keV} \leq \delta E_R \leq 160 \text{ keV},$$

and

$$^{16}\text{O}(Z = 0.02) : -150 \text{ keV} \leq \delta E_R \leq 200 \text{ keV},$$

where significant carbon production could still be maintained for all negative $\delta E_R$. In stars of solar metallicity, the production of $^{16}$O appears to be the limiting factor, as it is only possible in a roughly symmetric (though rather broad) envelope centered on the physical value of $E_R$.

Previously, the stellar simulations of Refs. [33,35] indicated that sufficient abundances of both carbon and oxygen are only possible for $\delta E_R \approx \pm 100$ keV around the empirical value $E_R = 379.47(18)$ keV. From the present results, we conclude that the energy of the Hoyle state is likely to be less fine-tuned than previously thought. However, if the Hoyle state is raised by more than $\simeq 300$ keV, the generation of sufficient oxygen would encounter difficulties. Were the Hoyle state located more than $\approx 500$ keV above its physical energy, the universe would also be unlikely to contain a sufficient amount of carbon.

4 Sensitivity to small changes in the fundamental parameters

We shall now update the ranges of variation of the light quark mass $\delta m_q$ and the fine-structure constant $\delta \alpha_{\text{em}}$, which are compatible with the formation of sufficient amounts of carbon and oxygen in our universe, and thus with the existence of carbon-oxygen based life. As in Ref. [3], we express the shift in the Hoyle state $\delta E_R$ as

$$\delta E_R \approx \frac{\partial E_R}{\partial E_R} \bigg|_{M_{\pi}^{ph}} \delta M_{\pi} + \frac{\partial E_R}{\partial \alpha_{\text{em}}} \bigg|_{\alpha_{\text{em}}^{ph}} \delta \alpha_{\text{em}}$$

$$\equiv Q_q(E_R) \left( \frac{\delta m_q}{m_q} \right) + Q_{\text{em}}(E_R) \left( \frac{\delta \alpha_{\text{em}}}{\alpha_{\text{em}}} \right),$$

for $|\delta m_q/m_q| \ll 1$ and $|\delta \alpha_{\text{em}}/\alpha_{\text{em}}| \ll 1$. We shall first consider the effects of varying $m_q$, for which we have

$$Q_q(E_R) \equiv \frac{\partial E_R}{\partial E_R} \bigg|_{M_{\pi}^{ph}} K_q^q M_{\pi}$$

and we recall that $K_q^q = 0.494^{+0.009}_{-0.013}$ [12]. As in the NLEFT calculation of Ref. [3], we find

$$\frac{\partial E_R}{\partial E_R} \bigg|_{M_{\pi}^{ph}} = -0.572(19) \tilde{A}_n - 0.933(15) \tilde{A}_t + 0.068(7),$$

where the only change from Ref. [3] is in the constant term, which has been recalculated using the updated values of $x_1$ and $x_2$. The numbers in parentheses denote Monte Carlo uncertainties, and as in Ref. [3], the relatively small additional errors due to the uncertainties of $x_1$ and $x_2$ have been neglected. As such uncertainties are much reduced here, this simplification is better justified.

The boundaries of the envelope where a sufficient abundance of carbon or oxygen is maintained are then

$$\delta E_R^{(-)} \leq Q_q(E_R) \left( \frac{\delta m_q}{m_q} \right) \leq \delta E_R^{(+)}$$

where the earlier stellar nucleosynthesis calculations of Refs. [33,35] indicated an overall bound of $|\delta E_R^{(+)}| = \delta E_R^{(+)} = 100$ keV from ad hoc variations of the Hoyle state energy. The present situation is slightly more involved, as the upper and lower boundaries are not symmetric, and moreover the boundaries for $^{12}$C and $^{16}$O are different, an additional factor being the (initial) metallicity of the star under consideration. On the one hand, for $E_R$ to not increase beyond the permissible range, we require that

$$-0.572(19) \tilde{A}_n - 0.933(15) \tilde{A}_t + 0.068(7)$$

$$\leq \frac{\delta E_R^{(+)}(\tilde{A}_n)}{K_q^q M_{\pi}} \left( \frac{\delta m_q}{m_q} \right)$$

for positive shifts in $m_q$ such that $\delta m_q \to |\delta m_q|$, and

$$-0.572(19) \tilde{A}_n - 0.933(15) \tilde{A}_t + 0.068(7)$$

$$\geq \frac{\delta E_R^{(+)}(\tilde{A}_n)}{K_q^q M_{\pi}} \left( \frac{\delta m_q}{m_q} \right)$$

for negative shifts in $m_q$ such that $\delta m_q \to -|\delta m_q|$. On the other hand, for $E_R$ to not decrease too much, we should
Fig. 2. “Survivability plots” based on the stellar simulations of Oberhummer et al., bottom right plot and [34,35] (all other plots). The data points with horizontal and vertical error bars indicate estimates of where our universe is located. On the solid black lines, $E_R$ (and hence the triple-alpha reaction) is independent of variations in $m_q$. The dot-dashed black lines correspond to the equalities (36) and (37), which mark the upper bound $\delta E_R^{(+)}$ for $|\delta m_q|/m_q = 1\%$. Similarly, the dotted black lines correspond to the equalities (38) and (39), which mark the lower bound $\delta E_R^{(-)}$. For the case of $^{12}$C and $Z = 0.02$, both $\delta m_q > 0$ and $\delta m_q < 0$ are given, for the other cases only $\delta m_q > 0$ is shown.

\[
\begin{align*}
\frac{\partial a}{\partial M} &< 0, \\
\frac{\partial a}{\partial m} &> 0, \\
\frac{\partial a}{\partial E} &> 0.
\end{align*}
\]

have

\[
\begin{align*}
-0.572(19)\: &\bar{A}_s - 0.933(15)\: \bar{A}_t + 0.068(7) \\
\geq & - \frac{\delta E_R^{(-)}}{K_{Mz_Mz}} \left( \frac{|\delta m_q|}{m_q} \right)^{-1}, \: \delta m_q > 0, \\
\leq & - \frac{\delta E_R^{(-)}}{K_{Mz_Mz}} \left( \frac{|\delta m_q|}{m_q} \right)^{-1}, \: \delta m_q < 0.
\end{align*}
\]

for positive shifts in $m_q$, and

\[
\begin{align*}
-0.572(19)\: &\bar{A}_s - 0.933(15)\: \bar{A}_t + 0.068(7) \\
\geq & - \frac{\delta E_R^{(-)}}{K_{Mz_Mz}} \left( \frac{|\delta m_q|}{m_q} \right)^{-1}, \: \delta m_q > 0, \\
\leq & - \frac{\delta E_R^{(-)}}{K_{Mz_Mz}} \left( \frac{|\delta m_q|}{m_q} \right)^{-1}, \: \delta m_q < 0.
\end{align*}
\]

for negative shifts in $m_q$. Hence, the values of $\bar{A}_s$ and $\bar{A}_t$ compatible with a given variation in $m_q$ are given by the regions enclosed by Eqs. (36) and (38) for $\delta m_q > 0$, and by Eqs. (37) and (39) for $\delta m_q < 0$.

The constraints on $A_s$ and $\bar{A}_t$ due to the conditions (36) through (39) are illustrated by the shaded bands in Fig. 2. These bands cover the values of $\bar{A}_s$ and $\bar{A}_t$ consistent with the ability of stars to produce $^{12}$C and $^{16}$O, when $m_q$ is varied by 0.5%, 1% and 5%. As an example, given the boundaries for $^{12}$C production in stars with solar metallicity ($Z = 0.02$), the interpolated lattice QCD result is compatible with a $\approx 0.8\%$ increase in $m_q$, beyond which $E_R$ is decreased too much. Conversely, beyond a $\approx 0.4\%$
decrease in $m_q$. $E_R$ is increased too much. For stars with solar metallicity, the production of $^{16}$O is clearly the most heavily constraining factor, although low-metallicity stars ($Z = 10^{-4}$) allow for much greater variation of $m_q$. This value of the metallicity corresponds to the metal-poorest stars observed in the universe. In such metal-poor stars, the chiral EFT determinations of $\bar{A}_k$ and $A_k$ suggest that changes of $\approx 5\%$ in $m_q$ are permissible. However, from the interpolated lattice QCD results, the allowed range in $m_q$ is strongly reduced to a mere $\approx 0.8\%$, largely because of the positive value of $A_k$.

Finally, we note that the effect of shifts in the electromagnetic fine-structure constant lead to the constraint

$$\frac{|\delta \alpha_{\text{em}}|}{\alpha_{\text{em}}} \leq \frac{|\delta E_R|}{Q_{\text{em}}(E_R)},$$

where $Q_{\text{em}}(E_R) = 3.99(9)$ MeV was determined in the NLEFT calculation of Ref. [6]. With the bound $|\delta E_R| = 100$ keV [34,35], this is compatible with a $\approx 2.5\%$ shift in $\alpha_{\text{em}}$. With the much more relaxed bound $|\delta E_R| = 300$ keV due to the production of $^{16}$O in stars with $Z = 10^{-4}$, this tolerance is significantly increased to $\approx 7.5\%$.

5 Discussion

We have reconsidered the sensitivity of the triple-alpha process with respect to shifts in the fundamental parameters of nature, especially the light quark mass $m_q$ and the electromagnetic fine-structure constant $\alpha_{\text{em}}$. Our knowledge of the quark-mass dependence of the hadronic parameters in the nuclear Hamiltonian has improved significantly, in particular with respect to the nucleon axial-vector coupling $g_A$. There, new lattice QCD data allow for an accurate chiral extrapolation which shows good convergence. Much more detailed predictions of the effects of $\alpha_{\text{em}}$ variation of the position of the Hoyle state resonance on the stellar yields of $^{12}$C and $^{16}$O have also become available. These show that the production of $^{16}$O in low-metallicity stars is likely to be the limiting factor, although the bounds on carbon-oxygen based life have in general become much less stringent. At the same time, much more lattice QCD data on the singlet and triplet S-wave nucleon scattering lengths at unphysical quark masses have been produced. The current lattice QCD data appear to exclude the no-fine-tuning scenario, to the extent that a relatively small $\approx 0.5\%$ shift in $m_q$ would eliminate carbon-oxygen based life from the universe. On the other hand, such life could possibly persist up to $\approx 7.5\%$ shifts in $\alpha_{\text{em}}$. Clearly, more reliable lattice QCD data at close-to-physical pion masses are required to overcome the remaining uncertainties discussed in detail in Sec. 2.

While we have here mostly focused on updating the nuclear, hadronic and astrophysical inputs to the EFT calculation of the fine-tuning of the triple-alpha process, it is also of interest to perform improved $^{12}$C simulations in NLEFT. Apart from effects of smearing of the LO operators, the EFT calculation of the triple-alpha process is essentially a LO calculation. Extending this to higher orders would require much more detailed information on the nuclear force at unphysical pion masses, for higher orders in the EFT expansion. However, as modern NLEFT potentials, see e.g. [39], use a combination of local and non-local smearing at LO, the description of $^{12}$C including the Hoyle state is nevertheless expected to be improved.

Acknowledgments

We are grateful to Evan Berkowitz for supplying the analysis of the pion mass dependence of $g_A$.
