We study the superfluid phase of the one-band attractive Hubbard model of fermions as a prototype of a strongly correlated s-wave fermion superfluid on a lattice. We show that the collective mode spectrum of this superfluid exhibits, in addition to the long wavelength sound mode, a sharp roton mode over a wide range of densities and interaction strengths. We compute the sound velocity and the roton gap within a generalized random phase approximation (GRPA) and show that the GRPA results are in good agreement, at strong coupling, with a spin wave analysis of the appropriate strong coupling pseudospin model. We also investigate, using this two-pronged approach, the breakdown of superfluidity in the presence of a supercurrent. We find that the superflow can break down at a critical flow momentum via several distinct mechanisms — depairing, Landau instabilities or dynamical instabilities — depending on the dimension, the interaction strength and the fermion density. The most interesting of these instabilities is a charge modulation dynamical instability which is distinct from previously studied dynamical instabilities of Bose superfluids. The charge order associated with this instability can be of two types: (i) a commensurate checkerboard modulation driven by softening of the roton mode at the Brillouin zone corner, or, (ii) an incommensurate density modulation arising from superflow-induced finite momentum pairing of Bogoliubov quasiparticles. We elucidate the dynamical phase diagram showing the critical flow momentum of the leading instability over a wide range of fermion densities and interaction strengths and point out implications of our results for experiments on cold atom fermion superfluids in an optical lattice.

I. INTRODUCTION

The study of strongly correlated fermionic superfluids is of interest in the context of solid state materials, such as cuprate and pnictide superconductors, as well as ultracold atomic gases in optical lattices. One of the key goals of condensed matter physics is to understand the nature of single particle and collective excitations in such strongly correlated systems. Another important problem is to elucidate the mechanisms by which superfluidity breaks down in these lattice systems — such an understanding would shed light on the critical current and on the nature of vortex cores in strongly interacting superfluids which are issues of significant experimental and theoretical interest. Moreover, the inverse critical superfluid momentum can be shown to be directly related to characteristic length scales, associated with the low-energy excitations in the system and can thus serve as a useful probe of these excitations. This is especially relevant for neutral cold atom superfluids, in which the critical flow is unaffected by complications such as disorder effects and current induced magnetic fields which are present in solid state superconductors. While there has been a significant amount of experimental and theoretical progress in understanding the breakdown of superflow for Bose superfluids in an optical lattice and for Fermi superfluids in the absence of a lattice potential, this issue has not been addressed in detail in the context of Fermi superfluids on a lattice.

In this paper we study the collective modes and the mechanisms for the breakdown of superflow in the one-band attractive Hubbard model which is a model Hamiltonian for strongly correlated s-wave Fermi superfluids on a lattice. The attractive Hubbard Hamiltonian,

\[ H = -t \sum_{\langle ij \rangle} (c_{i\sigma}^\dagger c_{j\sigma}^\dagger + c_{j\sigma} c_{i\sigma}) - \mu \sum_{i\sigma} n_{i\sigma} - U \sum_i (n_{i\uparrow} - \frac{1}{2})(n_{i\downarrow} - \frac{1}{2}), \tag{1} \]

describes fermions with spin \( \sigma \) hopping, with amplitude \( t \), between adjacent sites of a lattice, and interacting via an on-site attractive interaction \( U \). The chemical potential \( \mu \) tunes the fermion density away from half-filling at \( \mu = 0 \). Summation over repeated spin indices is implicit henceforth, and, unless stated explicitly, we will measure energies in units of \( t \). We will study this model on the square lattice in two dimensions (2D) and the cubic lattice in three dimensions (3D). The ground states of this model include the uniform superfluid (SF) and a “checkerboard” charge density wave (CDW), which is an insulating crystal. It is well known that this model has an enhanced “pseudospin symmetry” at the point \( \mu = 0 \), which leads to a degeneracy between the SF and the CDW ground states. Away from \( \mu = 0 \), this degeneracy is lifted and the SF ground state is energetically more favorable. One expects, however, that even when this pseudospin symmetry is only weakly broken, the excitation spectrum of the superfluid will exhibit signatures of proximity to the CDW ground state. One also expects that once superflow is imposed, there will be a critical flow velocity beyond which the kinetic energy of superflow will overcome the energy difference between the
stationary SF and the CDW. The superflow in this case is limited not by the pairing gap, which may be large, but by this energy difference, which becomes very small close to half-filling. This situation is similar to the one encountered, for example, in cuprate superconductors, where the superconducting ground state in the underdoped region of the phase diagram is proximate to the antiferromagnetic Mott insulator. Similar physics may also be relevant to Cu$_2$TiSe$_2$ where there is a competition between charge order and superconductivity.

This general idea motivates us to study the collective modes as well the stability of superflow in the SF phase of the attractive Hubbard model. We begin by studying the collective mode spectrum in the absence of superflow and find that there is indeed a large window of interactions and density where the collective mode spectrum exhibits, in addition to a sound mode, a well-defined roton minimum at wavevectors $\mathbf{Q} \equiv (\pi, \pi)$ (in 2D) or $\mathbf{Q} \equiv (\pi, \pi, \pi)$ (in 3D) arising from proximity to the CDW. The existence of such a roton minimum has been pointed out in earlier work. We present our results for the values of sound velocity and roton gap as functions of fermion filling and interaction strength. These results of the collective mode spectrum could potentially be verified in studies of collective modes in the superfluid phase of cold Fermi gases in an optical lattice. We then turn to a study of the stability of uniform superflow in the Hubbard model.

We elucidate a variety of superflow-breakdown mechanisms - depairing, Landau instabilities and dynamical instabilities. We observe Landau instabilities of the collective mode at incommensurate wavevectors as has also been reported in Ref. More importantly, we discover dynamical instabilities involving checkerboard or incommensurate stripe-like density modulations which are distinct from previously studied dynamical instabilities of Bose superfluids. We show that the checkerboard dynamical instability can be viewed as the result of the softening of the roton mode and that this instability has a simple analog in the strong-pairing model, which we discuss. In contrast, the incommensurate CDW instability occurs only at intermediate coupling strengths and has no analog in the strong-pairing pseudospin model. We explain this instability as a finite momentum pairing instability of Bogoliubov quasiparticles, somewhat analogous to the Halperin-Rice exciton condensate instability in indirect band-gap semiconductors. These dynamical instabilities could be experimentally probed by creating a “running” optical lattice as has been done for Bose superfluids.

The existence of the checkerboard dynamical instability was discussed earlier by us from the strong coupling perspective. The present paper goes considerably beyond our earlier work. The formalism that we use (the generalized random phase approximation or GRPA), allows us to address the entire range of interaction strengths from weak to strong coupling. We have checked that the GRPA results smoothly match on to the earlier analysis of the strong coupling pseudospin model and we present these comparisons where appropriate. Within this formalism we have obtained dynamical phase diagrams of the flowing superfluid over a wider range of interactions than in our previous study and uncovered the incommensurate CDW instability which was not reported in our earlier paper.

We have tried to make this paper fairly self-contained. We begin in Section II with an overview of some key general results on the Hubbard model. Section III focuses on the formalism which we use in the remainder of the paper. We then turn, in Section IV, to results for the collective mode spectrum in the absence of superflow. Section V contains the results for the instabilities of the flowing superfluid and the phase diagram showing the leading instabilities as a function of interaction and fermion density. Section VI contains a discussion of the experimental observability of our results in fermionic cold atom systems as well as possible implications of these results for vortex core physics in strongly correlated superfluids. We end, in Section VII, with a summary of our results and possible avenues for future research. Appendix A contains the Fourier transform convention which we use, Appendix B gives details of the GRPA formalism, and the mean field theory of the “flowing supersolid” state is discussed in Appendix C.

II. OVERVIEW OF THE MODEL

Before we turn to a study of collective modes and the stability of superflow using the Hubbard model Hamiltonian, we begin by reviewing some well known facts about the model which will serve to set the stage for our discussion in the remainder of this paper.

A. Pseudospin Operators and Pseudospin Symmetry

We start by defining pseudospin operators, first introduced in the context of the theory of superconductivity by Anderson.

\begin{align}
T^+_i &= \eta_i c^\dagger_{i\uparrow} c^\dagger_{i\downarrow}, \\
T^-_i &= \eta_i c_{i\downarrow} c_{i\uparrow}, \\
T^z_i &= \frac{1}{2}(c^\dagger_{i\uparrow} c_{i\downarrow} + 1),
\end{align}

where $\eta_i = +1$ on one sublattice and $\eta_i = -1$ on the other sublattice of the square or cubic lattice. The physical meaning of these operators is clear: $T^+_i$ creates a fermion pair at site $i$, $T^-_i$ annihilates a fermion pair at site $i$, and $T^z_i$ is the pair number operator. It is straightforward to check that these operators obey usual spin commutation relations. Furthermore, provided that $\mu = 0$, the global
pseudospin operators,
\[ T^z = \sum_i T^z_i, \]
\[ T^\pm = \sum_i T^\pm_i, \]
all commute with the Hubbard Hamiltonian in Eq. 11 so that there is a global pseudospin SU(2) symmetry at this special point. This is in addition to the ordinary global spin SU(2) symmetry which is present for any value of \( \mu \).

B. Ground States and Degeneracies

Quantum Monte Carlo simulations have shown that the ground state of the attractive Hubbard model is a uniform SF for generic values of \( U/t \) and \( \mu/t \). The uniform SF has an order parameter \( \langle c_i^\dagger c_i \rangle \sim \Delta e^{i\varphi} \) where a choice of the phase, \( \varphi \), of the order parameter corresponds to a spontaneously broken symmetry. In terms of pseudospin operators, this means that \( \langle T_i^z \rangle \sim \eta \Delta e^{i\varphi} \). For \( \mu = 0 \), the pseudospin symmetry discussed above leads to the conclusion that all states related to this SF ground state by a global pseudospin rotation are also valid ground states and are characterized by an order parameter \( N = \eta_i(T_i) \) which can point to any location on the Bloch sphere. The uniform SF state has \( N \) pointing to locations on the equator. The state with \( N \sim \pm \Delta z \), which points to the north/south pole of the Bloch sphere, corresponds to a checkerboard charge density wave state (CDW) of pairs. Other locations on the Bloch sphere correspond to states with coexisting CDW and SF orders.

C. Strong coupling pseudospin Hamiltonian

In the limit of large \( U/t \), each site on the lattice will have either no fermions or a pair of tightly bound fermions. Thus, any allowed fermion configuration will have \( T_i^z = \pm 1/2 \) at each site and the kinetic energy will lead to tunneling between such “classical” Ising configurations of the pseudospin. The pseudospin dynamics for \( U/t \gg 1 \) is then described by an effective pseudospin Hamiltonian:
\[ H_{\text{eff}} = J \sum_{\langle ij \rangle} T_i \cdot T_j - \mu \sum_i T_i^z, \]
where \( J = 4t^2/U \). For \( \mu = 0 \), this Hamiltonian reduces to a pseudospin Heisenberg model which manifestly exhibits the pseudospin SU(2) symmetry.

III. FORMALISM

The most general problem we would like to tackle, motivated by the issues discussed in the introduction, is to understand the collective mode spectrum of a flowing superfluid. We begin by setting up a two-pronged approach to attack this problem. At small values of \( U/t \), we build upon the mean field theory of the flowing superfluid to obtain the collective mode spectrum using GRPA. At strong coupling, we study the pseudospin model using Holstein-Primakoff spin wave theory. We find that the GRPA results smoothly match on to the results from spin wave theory of the pseudospin model as we increase \( U/t \), showing that the GRPA correctly captures aspects of the strong coupling limit. This suggests that the GRPA may be a very good approximation to compute the collective mode spectrum and address the breakdown of superfluid over the entire range of couplings.

A. Generalized Random Phase Approximation for the Attractive Hubbard Model

We begin by constructing the mean field theory of the uniform superconducting state of the attractive Hubbard model in the presence of nonzero superflow. The mean field Hamiltonian in the presence of a supercurrent is obtained by forming Cooper pairs with nonzero momentum,
\[ H_{\text{MFT}} = -t \sum_{\langle ij \rangle} (c_i^\dagger c_j + c_j^\dagger c_i) - \mu \sum_i n_i - \Delta_0 \sum_i \left( e^{iQ \cdot r} c_i^\dagger + e^{-iQ \cdot r} c_i \right), \]
where we have set \( U \langle c_i^\dagger c_i \rangle = \Delta_0 e^{iQ \cdot r} \) and absorbed the uniform Hartree shift into the chemical potential. In momentum space, the mean field Hamiltonian takes the form
\[ H_{\text{MFT}} = \sum_k \xi_k c_k^\dagger c_k - \Delta_0 \sum_k \left( c_k^\dagger c_{k+Q} + c_{k+Q}^\dagger c_k \right), \]
where \( \xi_k = -2t\epsilon_k - \mu \), with \( \epsilon_k = \sum_{i=1}^d \cos(k_i) \) (\( d = 2,3 \) is the dimensionality of the lattice).

We can diagonalize \( H_{\text{MFT}} \) by defining Bogoliubov quasiparticles (QPs), \( \gamma \), via
\[ \begin{pmatrix} c_k^\dagger \\ c_{-k+Q}^\dagger \end{pmatrix} = \begin{pmatrix} u_k(Q) & v_k(Q) \\ -v_k(Q) & u_k(Q) \end{pmatrix} \begin{pmatrix} \gamma_k^\dagger \\ \gamma_{-k+Q}^\dagger \end{pmatrix}. \]
For simplicity of notation, we will refer to the Bogoliubov transformation coefficients above as \( u_k, v_k \) with the implicit understanding that they depend on \( Q \). Parametrizing \( u_k \equiv \cos(\theta_k) \), \( v_k \equiv \sin(\theta_k) \), and demanding that the transformed Hamiltonian be diagonal leads to the condition
\[ \tan(2\theta_k) = \frac{\Delta_0}{\xi_k + \xi_{-k+Q}}. \]
Defining
\[ \Gamma_k = \sqrt{\frac{1}{4} (\xi_k + \xi_{-k+Q})^2 + \Delta_0^2}, \]
we find that the Bogoliubov transformation coefficients must satisfy the relations
\[ u_k^2 = \frac{1}{2} \left( 1 + \frac{\xi_k + \xi_{-k+Q}}{2\Gamma_k} \right), \]
\[ v_k^2 = \frac{1}{2} \left( 1 - \frac{\xi_k + \xi_{-k+Q}}{2\Gamma_k} \right), \]
\[ u_k v_k = \frac{\Delta_0}{2\Gamma_k}. \]
In terms of the Bogoliubov QPs, the mean field Hamiltonian finally takes the form
\[ H_{\text{MFT}} = E_{\text{GS}} + \sum_k E_k \gamma_k^\dagger \gamma_k, \]
where \( E_{\text{GS}} \) denotes the ground state energy of \( H_{\text{MFT}} \) and \( E_k \) denotes the Bogoliubov QP dispersion given by:
\[ E_k = \Gamma_k + \frac{1}{2} (\xi_k - \xi_{-k+Q}), \]
\[ E_{\text{GS}} = \sum_k (\xi_k - E_k). \]
Demanding self-consistency of the mean field theory yields the gap and number equations:
\[ \frac{1}{U} = \frac{1}{N} \sum_k \frac{1}{2\Gamma_k} (1 - n_F(E_k) - n_F(E_{-k+Q})), \]
\[ f = \frac{2}{N} \sum_k [u_k^2 n_F(E_k) + v_k^2 (1 - n_F(E_{-k+Q}))], \]
where \( f \) is the filling, i.e. the average number of fermions per site, and \( N \) is the total number of sites. For given \( U \), filling \( f \) and flow momentum \( Q \), these equations can be solved to obtain the SF order parameter \( \Delta_0 \) and the QP spectrum.

Going beyond mean field theory, we need to include fluctuations of the density and the superfluid order parameter, which we will do within GRPA. We begin by considering perturbing external fields that couple to the density and order parameter modulation operators as:
\[ H'_{\text{MFT}} = H_{\text{MFT}} - \sum_i [h_i(i,t) \hat{\rho}_i + h_\Delta(i,t) \hat{\Delta}(i,t) e^{iQ \cdot r_i} + h_\Delta^\ast(i,t) \hat{\Delta}^\dagger(i,t) e^{-iQ \cdot r_i}], \]
where
\[ \hat{\rho}_i = \frac{1}{2} c_{i\sigma}^\dagger c_{i\sigma}, \]
\[ \hat{\Delta}_i = c_{i1} c_{i1}. \]

FIG. 1: Illustrative example of the collective mode dispersion and quasiparticle-pair continuum in 2D, for zero superflow \( Q = 0 \) with \( U/t = 3 \) and \( f = 0.2 \) fermions per site, along the contour displayed in the inset.

Going to momentum space,
\[ H'_{\text{MFT}} = H_{\text{MFT}} - \frac{1}{N} \sum_k h_\alpha(K,t) \hat{O}_\alpha(K), \]
where \( \alpha = 1, 2, 3 \), summation over \( \alpha \) is implicit, and \( \hat{O}_\alpha(K) = \hat{\rho}(K) \Delta_{-K+Q} \Delta_{K+Q} \) is the vector of fermion bilinear operators corresponding to density and superfluid order parameters at nonzero momenta, with the order parameters given by:
\[ \hat{\rho}_K = \frac{1}{2} \sum_k c_{k\sigma}^\dagger c_{k+K\sigma}, \]
\[ \hat{\Delta}_K = \sum_k c_{-k+K\dagger \sigma} c_{k\sigma}^\dagger, \]
\[ \hat{\Delta}_K^\dagger = \sum_k c_{k\sigma}^\dagger c_{-k+K\dagger \sigma}. \]
The perturbing fields correspond to
\[ h_1(K,t) = h_\rho(K,t), \]
\[ h_2(K,t) = h_\Delta(K,t), \]
\[ h_3(K,t) = h_\Delta^\ast(-K,t). \]
We define the susceptibility matrix as
\[ \langle \hat{O}_\alpha(K,\omega) \rangle = \chi^0_{\alpha\beta}(K,\omega) h_\beta(K,\omega). \]
The derivation of this bare susceptibility matrix as well as the explicit expressions for the elements of this matrix are given in Appendix B.

In order to account for interaction effects at the GRPA level, we note that the interaction effectively induces internal fields which renormalize the applied external field so that the susceptibility within the GRPA can be expressed as:
\[ \chi^{\text{GRPA}}_{\alpha\beta} = (1 - U \chi^0 D)_{\alpha\beta}^{-1} \chi^0_{\alpha\beta}. \]
Here, \( D = \text{diag}(2,1,1) \) is a diagonal matrix that encodes the decoupling of the interaction Hamiltonian. The
derivation of this expression in explained in Appendix B. This GRPA susceptibility will diverge when the determinant $\text{Det}(1 - U \chi^0 D)$ becomes zero (or equivalently, one of the eigenvalues of this matrix vanishes). We identify the locus of real frequencies, $\omega \equiv \omega(K)$, where this happens, as the dispersion of a sharp (undamped) collective mode.

Fig. 1 provides an illustrative example of the collective mode spectrum obtained using the GRPA in 2D with $U/t = 3$ and a filling $f = 0.2$ fermions per site in the absence of superflow ($Q = 0$). We find a linearly dispersing superfluid “phonon” mode at small momenta and low energy. The slope of this linear dispersion is the sound velocity. The collective mode disperses as a function of momentum over the Brillouin zone and exhibits an extremum at the edges of the Brillouin zone. In the example here, it is a maximum at $K = (\pi, \pi)$, but with increasing interaction strength and at fillings closer to $f = 1$, the spectrum exhibits a minimum at $K = (\pi, \pi)$ arising from strong short distance density correlations. At high energies, there is an onset of a two-quasiparticle continuum where the collective mode can decay by creating two Bogoliubov quasiparticles with opposite spins in a manner which conserves energy and momentum. Once the collective mode energy goes above the lower edge of the two-particle continuum of Bogoliubov QP excitations, it will cease to be a sharp excitation and acquire a finite lifetime. The collective mode energy as well as the pair continuum change in the presence of superflow as discussed subsequently.

B. Strong Coupling Limit: Spin Wave Analysis of Pseudospin Model

In the pseudospin model, a state with nonzero supercurrent is obtained by imposing a phase twist on the non-flowing ground state $|0\rangle$ as

$$|Q\rangle = \exp \left[-i \sum_i T_i^z Q \cdot r_i\right] |0\rangle. \quad (21)$$

Equivalently, we can make a unitary transformation to work with the Hamiltonian

$$H_{\text{eff}}(Q) = J \sum_{(ij)} \left[T_i^x T_j^x + (T_i^x T_j^x + T_i^y T_j^y) \cos(Q \cdot r_{ij}) - \eta_i T_i^z \right], \quad (22)$$

where $r_{ij} \equiv r_i - r_j$. This amounts to transforming to a reference frame where the pseudospin is at rest.

The classical ground state $|0\rangle_c$, which is the ground state obtained under the assumption that the pseudospins are classical vectors, is equivalent to the mean-field ground state of the interacting fermion model and can be parametrized by specifying the classical vector $T_i^c$ at each lattice site. This is given by

$$T_i^c \equiv S(\eta_i \sin \theta, 0, \cos \theta), \quad (23)$$

where the pseudospin magnitude $S = 1/2$. The angle $\theta$ is related to the filling, $f$, defined earlier, as

$$f - 1 = \cos \theta. \quad (24)$$

Working at fixed filling, the chemical potential $\mu$ is given by

$$\mu = 2JS \cos(\theta)(\epsilon_0 + \epsilon_Q), \quad (25)$$

where $\epsilon_Q \equiv \sum_{i=1}^d \cos(Q i)$ as before.

We compute the excitations about the ground state $|0\rangle_c$ for the Hamiltonian $H_{\text{eff}}(Q)$ using a Holstein-Primakoff (HP) approach by rotating to new pseudospin operators $\bar{T}$ given by

$$\bar{T}_i^z = T_i^c \cos(\theta) + \eta_i T_i^z \sin(\theta),$$
$$\bar{T}_i^x = -T_i^c \sin(\theta) + \eta_i T_i^x \cos(\theta),$$
$$\bar{T}_i^y = \eta_i T_i^y, \quad (26)$$

FIG. 2: (Color online) Collective mode energy at zero superflow in 2D at strong coupling, $U/t = 15$. The dispersion is shown along the indicated contour in the Brillouin zone for different fillings: (a) $f = 0.8$ fermions per site and (b) $f = 1.0$ per site. The GRPA result (solid line) is in good agreement with the Holstein-Primakoff spin wave result (dashed line, HP) for the strong coupling pseudospin model. The roton minimum has a small gap at $f = 0.8$ but becomes a gapless mode at $f = 1.0$ due to the pseudospin SU(2) symmetry discussed in the text.
and expressing $\tilde{T}$ in terms of HP bosons. Expanding the Hamiltonian to $O(S)$, we find

$$H = E_c + \delta E_\alpha + \sum_K \omega_K(Q)b_K^\dagger b_K,$$  \hspace{1cm} (27)

where

$$E_c = -NJJ S^2 [\cos^2 \theta \epsilon_0 + (1 + \cos^2 \theta) \epsilon_Q],$$

$$\delta E_\alpha = \frac{JS}{2} \sum_K [\epsilon_K \sin^2 \theta - \frac{1 + \cos^2 \theta}{2} (\epsilon_{K+Q} + \epsilon_{K-Q})].$$ \hspace{1cm} (28)

represent, respectively, the classical ground state energy and the leading quantum correction to the ground state energy. The spin-wave dispersion $\omega_K(Q)$ is given by

$$\omega_K(Q) = 2JS (\beta_K(Q) + \sqrt{\alpha_K^2(Q) - \gamma_K^2(Q)}),$$ \hspace{1cm} (29)

with

$$\alpha_K(Q) = \epsilon_Q \sin^2 \theta \frac{\cos^2 \theta}{2} \frac{(1 + \cos^2 \theta)}{2} (\epsilon_{K+Q} + \epsilon_{K-Q}),$$

$$\beta_K(Q) = \frac{1}{2} \cos \theta (\epsilon_{K-Q} - \epsilon_{K+Q}),$$

$$\gamma_K(Q) = \frac{1}{4} \sin^2 \theta (2\epsilon_K + \epsilon_{K+Q} + \epsilon_{K-Q}).$$ \hspace{1cm} (30)

An illustration of the collective mode dispersions obtained using this approach is shown in Fig. 2 at a strong coupling value of the interaction $U/t = 15$ for two different fillings, $f = 0.8, 1.0$ fermions per site. We find that these dispersions are in good agreement with those obtained using the GRPA which serves to show that the GRPA also correctly captures aspects of the strong coupling limit. As seen from the dispersion, there is a linearly dispersing superfluid “phonon” mode at small $K$. In addition, for $f = 0.8$, we find a low energy “roton minimum” at $K = (\pi, \pi)$ which arises from strong local pair density correlations in the superfluid ground state. For $f = 1.0$, the gapless roton mode at $K = (\pi, \pi)$ is a manifestation of the pseudospin SU(2) degeneracy, discussed earlier, between the crystalline CDW ground state and the uniform superfluid ground state.

IV. COLLECTIVE MODES IN THE STATIONARY SUPERFLUID

We have seen that the collective mode spectrum obtained using the GRPA or the strong coupling analysis has a superfluid phonon mode at small momenta and a roton minimum at $K = (\pi, \pi)$ in 2D or at $K = (\pi, \pi, \pi)$ in 3D. The phonon mode is a reflection of the fact that the superfluid ground state breaks a global U(1) symmetry – it is thus the long wavelength Goldstone mode associated with this symmetry breaking. The roton mode arises from strong local density correlations, analogous to the roton mode in $^3$He. However, unlike in $^3$He, the rotons only exist at this commensurate wave vector on the lattice and do not form an incommensurate ring of wave vectors. Further, the roton mode becomes gapless at $\mu = 0$ and this gaplessness arises from a pseudospin SU(2) symmetry which leads to a degeneracy between the superfluid and CDW ground states as discussed earlier.

A. Sound Velocity

Fig. 3 shows the sound mode velocity $v_s$, extracted using the GRPA, over a range of densities and interaction strengths in 2D and 3D. In the limit of low filling and weak interaction, our calculations of $v_s$ agree with the results of Belkhir and Randeria, although strong finite size effects and a small pairing gap limit our numerical exploration of the very weak coupling regime $U/t \ll 1$. At strong coupling, $U/t \gg 1$, our results from the GRPA are in good agreement with the spin wave result $v_s = \sqrt{4U^2 / U} \sqrt{1 - N(0) \sqrt{2f - f^2}}$. The linear scaling of $v_s/t$ with $t/U$, expected for $U/t \gg 1$, is illustrated in the inset.
FIG. 4: (Color online) The energy of the collective mode at (a) $\pi, \pi$ in 2D and (b) $\pi, \pi, \pi$ in 3D for different interaction strengths. The dashed (solid) lines indicate that the mode energy corresponds to a local maximum (minimum) of the dispersion. The inset shows the collective mode energy in 3D at $(\pi, \pi, \pi)$ in 2D and $(\pi, \pi)$ in 3D. For low fillings and weak to intermediate coupling strengths, the mode energy shows a maximum at this momentum. For strong and weak to intermediate coupling strengths, the mode energy exhibits a local minimum and can be justifiably identified as a roton mode. The roton gap clearly scales as $t/U$ for $U/t \gg 1$ as seen from the inset of Fig. 4b.

B. Roton Gap

Fig. 4 shows the energy of the collective mode at $K = (\pi, \pi)$ in 2D and $K = (\pi, \pi, \pi)$ in 3D. For low fillings and weak to intermediate coupling strengths, the mode energy shows a maximum at this momentum. For strong enough interactions, or for fillings near $f = 1.0$, however, the mode energy exhibits a local minimum and can be justifiably identified as a roton mode. The roton gap clearly scales as $t/U$ for $U/t \gg 1$ as seen from the inset of Fig. 4b. Further, the roton energy goes to zero linearly as $f \rightarrow 1$. This is due to the chemical potential $\mu$, which tunes the filling $f$ away from half-filling, and explicitly breaks the pseudospin SU(2) symmetry present at $f = 1$.

V. SUPERFLOW INSTABILITIES

Superflow instabilities are easily understood in the context of bosonic superfluids possessing Galilean invariance. Superflow can then be simply thought of as a Galilean boost performed on a stationary SF. The excitations in the flow frame are the same as those of the stationary SF, except their energies undergo a Doppler shift. At a certain critical flow velocity, the Doppler shift renders the excitations gapless at some momentum. These gapless excitations are then populated, flow energy is transferred to these bosonic excitations, and superfluidity is lost. The critical velocity is given by $v_{\text{crit}} = \min(\omega_q/q)$, where $\omega_q$ is the energy of an excitation of the stationary SF at momentum $q$.

Our system, a paired fermionic superfluid on a lattice, is much richer. The excitations are fermionic Bogoliubov quasiparticles and a bosonic collective mode, corresponding to coupled quantum-mechanical fluctuations of the superfluid order parameter and the density. The effect of flow is now more than simply introducing a Doppler shift in excitation energies since the system explicitly breaks Galilean invariance. The SF order parameter and the quasiparticle dispersion of the mean field theory are strongly renormalized. In addition, the collective mode dispersion also changes strongly. This is easily seen in the strong coupling pseudospin model, where the dispersion of spin wave collective modes is given by Eq. (29). The term $\beta_K(Q)$ in this equation is the Doppler shift and clearly depends on the flow momentum. However, the terms $\alpha_K(Q)$ and $\gamma_K(Q)$ are strong functions of the flow momentum too. Further, on the lattice as opposed to the continuum, the Doppler shift vanishes at momentum points corresponding to the Brillouin zone edges. The only effect of superflow in this case is to cause a strong dispersion renormalization via its effect, at strong coupling, on $\alpha_K(Q), \gamma_K(Q)$.

Due to these effects of imposed superflow, our system undergoes three broad kinds of instabilities, which we call “depairing”, “Landau” and “dynamical”. Below, we describe each of these and map out a stability “phase diagram” as a function of dimensionality, interaction strength and density, indicating the critical flow momentum beyond which the uniform flowing superfluid is unstable. Here we will restrict our attention to superflow momenta $Q = Q_x \hat{x}$.

A. Depairing Instability

The system undergoes a depairing instability when the self-consistently calculated SF order parameter, $\Delta$, vanishes in the mean field theory of the flowing SF. At the critical flow momentum, the energy cost of flow outweighs the condensation energy gain, and the system goes into an unpaired normal state.

This instability is close to, but not identical with, the quasiparticles becoming gapless due to the flow-induced
Doppler shift. In 2D, we find that these two phenomena occur at the same value of the flow momentum. In 3D however, superfluidity persists beyond the point where quasiparticles become gapless. There is a small window of *gapless superfluidity*, where negative energy Bogoliubov quasiparticle states are occupied. This is analogous to what has been claimed to occur, for instance, in superfluid $^3$He in the presence of superflow. In this case, although there are negative energy quasiparticle excitations, the system cannot arbitrarily lower its energy by occupying such states since the Bogoliubov excitations are fermionic. The gapless superfluid thus survives as a stable intermediate phase in 3D.

### B. Landau Instability

A Landau instability occurs when the collective mode energy hits zero and becomes negative, as shown in Fig. 5. In the strong coupling limit, with the collective mode dispersion given in Eq.(29), this case is described by

$$\omega_K(Q) \geq \gamma_K(Q) \quad \text{and} \quad \beta_K(Q) < -\sqrt{\alpha_K(Q) + \gamma_K(Q)}.$$  

In the GRPA approach, we find that the renormalized susceptibility, $\chi^{\text{GRPA}}$, diverges for two real negative frequencies. These frequencies match smoothly onto the results of the spin wave frequencies at strong coupling.

As discussed in Ref. [23], Landau instability is not an instability of linearized dynamics of small fluctuations around the uniformly flowing state, since some form of mode coupling is necessary to transfer the energy of the superflow into these negative-energy modes. Its full theoretical description is thus rather complicated. Here we restrict ourselves to only finding the critical flow momentum for this instability.

We find that the Landau instability occurs either at small momenta, corresponding to the dispersion of the sound mode going below zero, or at some finite incommensurate momentum. In the case of low filling, unless preempted by depairing, we see a Landau instability of the sound mode. For moderate values of $U$ and the filling, we see Landau instabilities at large incommensurate momenta (as in Fig. 4). As the filling is reduced, this incommensurate wavevector moves towards the Brillouin zone centre, so that in the low density limit, it is the long wavelength sound mode that becomes unstable. Similar incommensurate instabilities have also been found in Ref. [22].

### C. Dynamical Instability

The underlying lattice potential allows for a new possibility for the breakdown of superflow, namely through dynamical instabilities. This corresponds to the eigen-frequency of the collective mode dispersion in our system becoming zero, and subsequently becoming complex.

The concept of dynamical instability is particularly simple to understand for weakly interacting bosons. In this case, the instability coincides with the point where the effective mass of the bosons changes sign as a function of the superflow momentum, leading to runaway growth of phase and density fluctuations which eventually destroy superfluidity.

For strongly interacting bosons the situation is more interesting. It has been shown that with increasing interaction strength at a commensurate filling (integer number of bosons per site), the dynamical instability occurs at a smaller and smaller superflow momentum. The critical flow momentum eventually tends to zero at the equilibrium superfluid to Mott insulator transition, scaling as the inverse of the divergent correlation length associated with this Mott transition.

Here, in the fermionic analog of the problem of the critical superflow in a strongly correlated superfluid, we...
find, in addition, an entirely different kind of dynamical instability, associated with emergent density-wave order for a large range of fillings, wherein the mode energies become complex at nonzero wavevectors. In the strong coupling limit, this happens when $|\omega_{\mathbf{K}}(\mathbf{Q})|$ becomes smaller than $|\gamma_{\mathbf{K}}(\mathbf{Q})|$. In the GRPA approach, at a dynamical instability, we find no real frequency at which any eigenvalue of the inverse GRPA susceptibility vanishes. The GRPA results for the critical flow momentum $\mathbf{Q}$, and the wavevector $\mathbf{K}$ at which the dynamical instability occurs, match smoothly onto the spin wave results at strong coupling. In this limit it is easy to check analytically that the dynamical instability associated with this emergent charge order is not preempted by a Landau instability.

The appearance of complex collective mode frequencies indicates an exponential growth of density fluctuations around the uniformly flowing state, at a wavevector $\mathbf{K}$.

We find two kinds of such dynamical instabilities — associated with commensurate (Fig. 6) or incommensurate (Fig. 7) charge order. We see the former for a large range of fillings in the vicinity of $f = 1$, for all interaction strengths. The wavevector at which this instability happens is at the Brillouin zone corner $- (\pi, \pi)$ in 2D and $(\pi, \pi, \pi)$ in 3D. This corresponds to an instability towards a “checkerboard” CDW state, with a density modulation of opposite sign on the two sublattices of the square or cubic lattice. The incommensurate dynamical instability, on the other hand, occurs at wavevectors corresponding to various incommensurate ordering patterns and it arises as follows. In the presence of superflow, the dispersion of the Bogoliubov quasiparticles is renormalized and Doppler shifted, giving rise to multiple minima separated by a nonzero wavevector. This leads to a peak in the bare mean field susceptibility, $\chi^0$ at this momentum. The interaction renormalizes this peak into a divergence and leads to a finite momentum pairing instability of Bogoliubov quasiparticles. This dynamical incommensurate instability is thus a non-trivial, interaction-driven phenomenon, which only occurs at intermediate coupling strength. This phenomenon is somewhat analogous to the formation of excitonic condensates in indirect band-gap semiconductors.

D. Stability phase diagrams

Taking these instabilities into account, we map out superflow stability phase diagrams in 2D (Fig. 8) and 3D (Fig. 9). These plots show the first instability that is encountered as imposed flow is increased, for different values of filling. Values of $U$ for the plots have been chosen so as to illustrate all possibilities. We see that the commensurate dynamical “checkerboard” CDW instability comes into play around $f = 1/2$ for all values of the interaction strength and is the dominant instability all the way to $f = 1$, where the critical flow momentum vanishes, reflecting the degeneracy between the SF and CDW states.

In the low density limit, the system is similar to a continuum Fermi gas. In 3D, the density of states at the Fermi level vanishes. At low interaction strength, this leads to the pairing gap $\Delta$ being exponentially suppressed. The sound velocity, on the other hand, is proportional to the Fermi velocity, so that $v_s \sim f^{1/3}$. This leads to a rather sharp drop of the sound velocity as $f \rightarrow 0$ but the gap drops to zero much faster. Therefore, in the 3D case, at weak interaction and low filling, a small imposed flow will drive $\Delta$ to zero before the flow velocity exceeds the sound velocity, leading to a depairing instability as can be seen in Fig. 9.

In contrast, in the low density continuum limit in 2D, the density of states goes to a constant, which means the
pairing gap stays finite as \( f \to 0 \). With imposed flow, the first instability that one encounters is then the Landau instability, which will happen when the flow velocity exceeds the sound velocity which scales as \( v_s \sim f^{1/2} \). We have not been able to numerically uncover the Landau instability in this regime due to severe finite size effects.

At intermediate densities, and at intermediate values of the interaction strength, the leading instability is the incommensurate dynamical instability, corresponding to the emergence of an incommensurate CDW, characterized by a wavevector which depends on the density and the interaction strength. This instability does not happen in either the strong-coupling limit, where the Anderson pseudospin description is appropriate\(^{23}\) nor in the weak-coupling BCS superfluid limit, where the instability at intermediate densities is due to depairing. This dynamical instability is a nontrivial intermediate-coupling phenomenon and is one of the most interesting results reported in this work.

An interesting question that arises in relation to the emergent CDW-driven dynamical instabilities, is the fate of the system beyond the critical flow momentum. We show, in Appendix C, that beyond the commensurate CDW dynamical instability threshold the system behaves as a “flowing supersolid” at the mean field level. However, we argue that fluctuations beyond mean field theory are expected to destroy this flowing supersolid. An explicit example of this, in the strong coupling limit, has been discussed by us earlier.\(^{23}\) We expect the same to be true in the case of the incommensurate CDW dynamical instability.
As shown, the instability first encountered as the flow is increased is the depairing instability, which occurs at an incommensurate wavevector and has no phase relationship with the superflow current. Another very interesting dynamical instability occurs at a commensurate wavevector corresponding to the corner of the Brillouin zone. This dynamical instability occurs at a commensurate wavevector and is a consequence of the degeneracy between SF and “checkerboard” CDW ground states at $f = 1$. Another very interesting dynamical instability occurs at a incommensurate wavevector and has no phase relationship with the superflow current.

VI. EXPERIMENTAL IMPLICATIONS

Assuming that future experiments will be able to produce attractive cold Fermi gases in the lowest band of an optical lattice, it is reasonable to expect that the ground state and low energy excitations of such a system will be well described by the attractive Hubbard model. Our results are also of relevance for the vortex-core physics in strongly-correlated lattice superfluids. Considering the vortex core as simply the region where the superflow is imposed on the system, depairing and Landau instabilities arise. In addition, this competition leads to dynamical instabilities corresponding to roton mode softening. This dynamical instability occurs at a commensurate wavevector corresponding to the corner of the Brillouin zone. This instability is easily described in the strong coupling pseudospin language and is a consequence of the degeneracy between SF and “checkerboard” CDW ground states at $f = 1$. Another very interesting dynamical instability occurs at an incommensurate wavevector and has no phase relationship with the superflow current.

VII. CONCLUSIONS

In conclusion, we have studied the SF ground state of the negative-U Hubbard model on a square and cubic lattice. Using GRPA, we have studied the collective mode spectrum at all values of the interaction strength and density. We have shown that strong density correlations at increasing filling lead to the appearance of roton features in the collective mode spectrum, which signal developing competition between uniform SF and density-ordered CDW states. When superflow is imposed on the system, depairing and Landau instabilities arise. In addition, this competition leads to dynamical instabilities corresponding to roton mode softening. This dynamical instability occurs at a commensurate wavevector corresponding to the corner of the Brillouin zone. This instability is easily described in the strong coupling pseudospin language and is a consequence of the degeneracy between SF and “checkerboard” CDW ground states at $f = 1$. Another very interesting dynamical instability occurs at an incommensurate wavevector and has no phase relationship with the superflow current.
strong coupling analog. It occurs over a range of densities near \( f = 1/2 \) and at intermediate values of the interaction strength. Our results may be verified in experiments with ultracold fermions loaded on an optical lattice. Interesting avenues to explore in the future would include extending this work to other lattice geometries\(^{32}\) and to study superflow instabilities in multiband superfluids\(^{33}\).

APPENDIX A: FOURIER TRANSFORM CONVENTIONS

We have Fourier transformed fermion operators as

\[
c_{\mathbf{i},\sigma} = \frac{1}{\sqrt{N}} \sum_{\mathbf{k}} c_{\mathbf{k},\sigma} e^{i\mathbf{k} \cdot \mathbf{r}_i}. \tag{A1}
\]

This defines the Fourier transform relations of our modulation operators as

\[
\hat{\rho}_i = \frac{1}{N} \sum_{\mathbf{K}} \hat{\rho}_\mathbf{K} e^{i\mathbf{K} \cdot \mathbf{r}_i}, \tag{A2}
\]

\[
\hat{\Delta}_i = \frac{1}{N} \sum_{\mathbf{K}} \hat{\Delta}_\mathbf{K} e^{i\mathbf{K} \cdot \mathbf{r}_i}, \tag{A3}
\]

where the momentum space operators \( \hat{\rho}_\mathbf{K} \) and \( \hat{\Delta}_\mathbf{K} \) are given in Eq.\(^{17}\).

Also, the real space fields that couple to our modulation operators are Fourier transformed as

\[
h_{\rho/\Delta}(i, t) = \frac{1}{N} \int \frac{d\omega}{2\pi} \sum_{\mathbf{q}} h_{\rho/\Delta}(\mathbf{q}, \omega) e^{i(\mathbf{q} \cdot \mathbf{r}_i - \omega t)}. \tag{A5}
\]

These Fourier transforms have been used in going from Eq.\(^{13}\) to Eq.\(^{16}\).

APPENDIX B: DETAILS OF THE GENERALIZED RANDOM PHASE APPROXIMATION

Let us assume that we have a Hamiltonian \( H_0 \) which is modified by a set of weak time-dependent perturbations so that

\[
H(t) = H_0 - \frac{1}{N} \sum_{\mathbf{K}} h_\alpha(\mathbf{K}, t) \hat{O}_\alpha(\mathbf{K}), \tag{B1}
\]

where the perturbation is assumed to be Hermitian. Using time-dependent perturbation theory to leading order in the perturbing fields, one finds that the change in the expectation value of the operator \( O_\alpha(\mathbf{K}) \) is given by:

\[
\delta\langle \hat{O}_\alpha(\mathbf{K}, t) \rangle = \int_{-\infty}^{+\infty} dt' \chi_{\alpha\beta}(\mathbf{K}, t-t') \langle \hat{O}_\beta(\mathbf{K}, t') \rangle, \tag{B2}
\]

where

\[
\chi_{\alpha\beta}(\mathbf{K}, t-t') = \frac{1}{N} \sum_n \frac{\langle \hat{O}_\beta(\mathbf{K}, t) \hat{O}_\alpha(\mathbf{K}, t') \rangle - \langle \hat{O}_\beta(\mathbf{K}, t) \rangle \langle \hat{O}_\alpha(\mathbf{K}, t') \rangle}{\omega_n - \omega + \frac{i\hbar}{2} \delta(t-t')}. \tag{B3}
\]

Here \([..] \) denotes the commutator and \( \langle ... \rangle \) implies that the expectation value is taken in the ground state of \( H_0 \). Upon doing a spectral decomposition, one obtains:

\[
\chi_{\alpha\beta}(\mathbf{K}, \omega) = \frac{1}{N} \sum_n \frac{\langle \hat{O}_\beta(\mathbf{K}, t) \hat{O}_\alpha(\mathbf{K}, t') \rangle}{\omega_n - \omega + \frac{i\hbar}{2} \delta(t-t')} \tag{B4}
\]

Here \( \langle \hat{O} \rangle_{mn} \equiv \langle m | \hat{O} | n \rangle \), and \( | n \rangle, | m \rangle \) denote the eigenstates of \( H_0 \) (with \( n = 0 \) corresponding to the ground state). In the denominator, \( E_{n0} \equiv E_n - E_0 \) where \( E_n \) is the energy of state \( | n \rangle \).

We are interested in the case where \( H_0 = H_{\text{MFT}} \), with the operators \( \hat{O}_\alpha(\mathbf{K}) \) given by

\[
\hat{O}_\alpha(\mathbf{K}) = \hat{\rho}_{-\mathbf{K}}, \quad \hat{O}_\alpha(\mathbf{K}) = \hat{\Delta}_{-\mathbf{K}+\mathbf{Q}}, \quad \hat{O}_\alpha(\mathbf{K}) = \hat{\Delta}^\dagger_{\mathbf{K}+\mathbf{Q}}, \tag{B5}
\]

and the perturbing fields corresponding to

\[
h_1(\mathbf{K}, t) = h_\rho(\mathbf{K}, t), \quad h_2(\mathbf{K}, t) = h_\Delta(\mathbf{K}, t), \quad h_3(\mathbf{K}, t) = h_\Delta(-\mathbf{K}, t). \tag{B6}
\]

At zero temperature, it is easily checked that the quasiparticle energies are all positive in the dynamically stable region of interest. In this case, the only terms which have nonzero matrix elements in the expression for \( \chi_{\alpha\beta}(\mathbf{K}, \omega) \) are those where the operators create two Bogoliubov quasiparticles (QPs) when acting on \( | 0 \rangle \) and where they destroy two Bogoliubov QPs when acting on \( | n \rangle \). It is therefore convenient to resolve each perturbation operator into two parts – one that creates two QPs and one
that annihilates two QPs – as follows:

\[ \hat{\rho}^{\gamma-K} = \frac{1}{2} \sum_{k} (u_k - K + u_k K + u_k K u_k K) \gamma_{-k+K+Q}, \]

\[ \hat{\rho}^{\gamma-K} = \frac{1}{2} \sum_{k} (u_k - K + u_k K + u_k K K) \gamma_{-k+K+Q}, \]

\[ \hat{\Delta}^{\Delta K+Q} = - \sum_{k} u_k u_k K \gamma_{-k+K+Q} \gamma_{-k+K+Q}, \]

\[ \hat{\Delta}^{\Delta K+Q} = \sum_{k} u_k u_k K \gamma_{-k+K+Q} \gamma_{-k+K+Q}, \]

\[ \hat{\Delta}^{\Delta K+Q} = \sum_{k} u_k u_k K \gamma_{-k+K+Q} \gamma_{-k+K+Q}, \]

\[ \hat{\Delta}^{\Delta K+Q} = - \sum_{k} u_k u_k K \gamma_{-k+K+Q} \gamma_{-k+K+Q}. \]

where the superscript ‘c’ denotes creation of 2 quasiparticles, and ‘a’ denotes annihilation.

Since \( \chi^0 \) is a symmetric matrix, it suffices to use the above to compute the following distinct elements:

\[ \chi_{1,1}^0 = \frac{1}{4N} \sum_{k} \left[ \frac{(u_k - K u_k + v_k - K v_k u_k u_k)}{\omega + E_k - K + E_{-k+Q}} \right], \]

\[ \chi_{1,2}^0 = \frac{1}{2N} \sum_{k} \left[ \frac{(u_k - K u_k + v_k - K v_k u_k u_k)}{\omega + E_k - K + E_{-k+Q}} \right], \]

\[ \chi_{1,3}^0 = \frac{1}{2N} \sum_{k} \left[ \frac{(u_k - K u_k + v_k - K v_k u_k u_k)}{\omega + E_k - K + E_{-k+Q}} \right], \]

\[ \chi_{2,2}^0 = \frac{1}{N} \sum_{k} \left[ \frac{u_k^2 u_k^2}{\omega + E_k - K + E_{-k+Q}} \right], \]

\[ \chi_{2,3}^0 = \frac{1}{N} \sum_{k} \left[ \frac{u_k^2 u_k^2}{\omega + E_k - K + E_{-k+Q}} \right], \]

\[ \chi_{3,3}^0 = \frac{1}{N} \sum_{k} \left[ \frac{u_k^2 u_k^2}{\omega + E_k - K + E_{-k+Q}} \right]. \]

In order to include interaction effects within the GRPA, we note that the interaction can be decomposed as follows:

\[ -U c_i^\dagger c_i^\dagger c_i c_i \rightarrow -U \left[ (c_i^\dagger c_i) c_i^\dagger c_i + (c_i^\dagger c_i) c_i^\dagger c_i \right], \]

\[ -U \left[ (c_i^\dagger c_i) c_i^\dagger c_i + (c_i^\dagger c_i) c_i^\dagger c_i \right] \] (B9)

These expectation values, generated by interactions in the presence of external fields, act as “internal fields” which renormalize the applied field. It is easy to show that this effect can be taken into account by simply setting

\[ h_1(K, \omega) \rightarrow h_1(K, \omega) + 2U \langle \hat{O}_1(K, \omega) \rangle, \]

\[ h_2(K, \omega) \rightarrow h_2(K, \omega) + U \langle \hat{O}_2(K, \omega) \rangle, \]

\[ h_3(K, \omega) \rightarrow h_3(K, \omega) + U \langle \hat{O}_3(K, \omega) \rangle. \]

(B10)

This leads to:

\[ \delta(\hat{O}_a) = \chi_{a\beta}^0 (h_\beta + UD_{\beta\gamma}(\delta(\hat{O}_\gamma))), \]

(B11)

where \( D \equiv \text{Diag}(2,1,1) \) is a diagonal matrix, and we have suppressed \((K, \omega)\) labels for notational simplicity. Solving the above equation gives:

\[ \delta(\hat{O}_a) = [(1 - U \chi^0 D)^{-1} \chi^0]_{a\beta} h_\beta \equiv \chi_{a\beta}^{\text{GRPA}} h_\beta, \]

(B12)

where \( \chi_{a\beta}^{\text{GRPA}} \) is the renormalized GRPA susceptibility.

APPENDIX C: MEAN FIELD THEORY OF THE FLOWING SUPERSOLID

For all values of the interaction strength and for fermion densities near \( f = 1 \), we clearly see a dynamical instability at the commensurate “checkerboard” wavevector - (\( \pi, \pi \)) in 2D and (\( \pi, \pi, \pi \)) in 3D. At this instability, we expect “checkboard” density order to arise beyond critical flow, leading to a state with coexisting SF and density order, a “flowing supersolid” \cite{22}. We study the mean field theory of this state in order to examine its stability. In the presence of a nonzero SF flow, imposed as a uniform phase gradient on \( \Delta \), we self-consistently calculate the ground state allowing for “checkboard” density modulations.

The mean field order parameters are:

\[ \Delta \equiv \frac{U}{N} \sum_k \langle \hat{c}_{k+Q} \hat{c}_k \rangle, \]

\[ \bar{\rho} \equiv \frac{U}{2N} \sum_k \langle \hat{c}_k^\dagger \hat{c}_{k+\Pi} \rangle, \]

\[ \bar{\Delta} \equiv \frac{U}{N} \sum_k \langle \hat{c}_{k+Q} \hat{c}_k \rangle, \]

(C1)

where \( \Pi \equiv (\pi, \pi) \) in 2D or \( (\pi, \pi, \pi) \) in 3D. Since there are no spin-selective Zeeman terms, we are justified in forcing the density modulation to be equal for both spin species. Due to global phase rotation \( U(1) \) symmetry, we
can choose $\Delta$ to be real but we allow $\tilde{\Delta}$ to be complex. $
abla\rho$, being the expectation value of the staggered density, is real.

Upto an unimportant constant, the Hamiltonian can then be written as:

$$H = \sum_k \psi_k^* \hat{H}(k) \psi_k,$$

where the primed summation in the Hamiltonian indicates that if $k$ is included, then $k + \Pi$ is to be excluded. The other notation is as follows:

$$\psi_k = \begin{pmatrix} c_k \\ c_{-k+Q}^\dagger \\ c_{k+\Pi}^\dagger \\ c_{-k-\Pi+Q}^\dagger \end{pmatrix},$$

and

$$\hat{H} = \begin{pmatrix} \xi_k & -\Delta & -\tilde{\rho} & -\tilde{\Delta} \\ -\Delta & -\xi_{k+Q} - \Delta^* & \tilde{\rho} & \tilde{\Delta} \\ -\tilde{\rho} & -\Delta & \xi_{k+\Pi} & -\Delta \\ -\Delta^* & \tilde{\rho} & -\Delta & -\xi_{-k-\Pi+Q} \end{pmatrix}. \quad \text{(C4)}$$

For given $U$, $Q$ and the density, we numerically diagonalize this matrix and solve the self-consistency equations for $\Delta$, $\tilde{\rho}$, $\tilde{\Delta}$ and the filling $f$. We then evaluate the superfluid and density order parameters in the converged solution. In addition, we also evaluate the uniform current,

$$\langle \hat{J} \rangle = -2t \sum_k c_{k\sigma}^\dagger c_{k\sigma} \nabla_k \epsilon_k$$

where $-2t\epsilon_k$ is the non-interacting fermion dispersion.

A “flowing supersolid” phase is indicated by simultaneous non-zero values for $\Delta$ and $\tilde{\rho}$. For the case of checkerboard order we do see a “flowing supersolid” phase beyond a critical flow momentum. However, the onset of density order coincides with a maximum in the expectation value of the current as a function of flow momentum (Fig. 10). This indicates that the system is dynamically unstable to the exponential growth phase and density fluctuations. The argument below demonstrates why this is the case in a simpler context.

Let us consider a superfluid system in 1D for simplicity. Denoting the mean field density and phase of the SF order parameter by $n_0$ and $\phi_0$ respectively, we consider fluctuations $\delta n$ and $\delta \phi$. Now, the current is some function of the gradient of the phase:

$$\langle \hat{J} \rangle = J \left( \frac{d\phi}{dx} \right).$$

The equations governing the dynamics of the fluctuations are the Josephson relation and the continuity equation. The former gives:

$$\frac{dn}{dt} = -\frac{dJ}{dx}.$$ 

Substituting $n = n_0 + \delta n$ and $\frac{d\phi\ }{dx} = Q + \frac{d\phi\ }{dx}$, we obtain

$$\frac{d\delta n}{dt} = -\frac{dJ}{dQ} \frac{d^2\delta \phi}{dxdx^2}. \quad \text{(C8)}$$

Combining this with the Josephson relation, we finally obtain:

$$\frac{1}{\alpha} \frac{d^2\delta \phi}{dt^2} = \frac{dJ}{dQ} \frac{d^2\delta \phi}{dxdx^2} \quad \text{(C9)}$$

When $dJ/dQ$, becomes negative, the wave-like solutions of this equation develop complex frequencies. In this case, density and phase fluctuations will grow exponentially in time making the system dynamically unstable when the current goes through a maximum as a function of the flow momentum $Q$.
