Alcohol Intake and Weight Loss During Intensive Lifestyle Intervention for Adults with Overweight or Obesity and Diabetes

Ariana M. Chao1,2, Thomas A. Wadden2, Jena Shaw Tronieri2, and Robert I. Berkowitz2,3

Objective: This study aimed to assess whether alcohol consumption decreases during an intensive lifestyle intervention (ILI) and whether alcohol consumption is associated with weight loss among participants with overweight or obesity and type 2 diabetes.

Methods: Participants (n=4,901) were from the Action for Health in Diabetes (Look AHEAD) study, a randomized controlled trial that compared an ILI with a diabetes support and education (DSE) control. Mixed-effects models were used to estimate the effect of the ILI on alcohol consumption and the influence of alcohol consumption on weight loss at year 4.

Results: ILI and DSE participants did not differ in changes in alcohol consumption. Alcohol intake was not associated with weight loss at year 1 of the ILI. ILI participants who abstained from alcohol lost 5.1% ± 0.3% of initial weight at year 4 compared with a significantly (P=0.04) smaller 2.4% ± 1.3% for consistent heavy drinkers. ILI participants who abstained from alcohol consumption over the 4 years lost 1.6% ± 0.5% more weight relative to individuals who drank alcohol at any time during the intervention (P=0.003). DSE participants did not differ in weight loss by alcohol consumption.

Conclusions: Heavy alcohol drinkers are at risk for suboptimal long-term weight loss. Decreasing alcohol consumption may improve weight management among individuals with diabetes.

Introduction

Alcoholic beverages are a top contributor of calories in Americans’ diets (1). The percentage of people who consume alcohol has increased since the early 2000s (2,3). More than 70% of Americans report consuming alcohol at least once a year (2,3). The per capita intake from alcoholic beverages is 109 kcal/d (4). A meta-analysis of prospective observational studies demonstrated that relative to individuals who drank minimal alcohol, light to moderate alcohol consumption was associated with a lower risk of type 2 diabetes (5).

However, alcohol is energy dense, containing 7.1 kcal/g, and may be an important factor related to weight. Alcohol is inefficient in facilitating satiety, and calories from alcohol usually add, rather than substitute,
for energy ingested through other dietary sources (6,7). Consumption of alcohol is linked to disinhibited eating (8) and increased food intake (9,10), possibly through neural mechanisms related to energy regulation (8,11). Some studies have supported a relationship between increased alcohol consumption and higher body weight (12-16), while others have suggested an inverse relation (17) or no association (7,18-20). Possible reasons for these discrepancies include the use of self-reported height and weight, variable (and often short) follow-up, and inconsistent control for confounders such as smoking status.

Though the association between alcohol consumption and body weight is unclear, decreasing or eliminating calories from alcohol is typically recommended during weight loss. Despite the potential benefits of reducing alcohol consumption on weight management, few studies have examined whether participants report changes in alcohol intake during weight loss treatment (21-23) and whether alcohol influences weight loss. One study demonstrated no change in alcohol intake during a lifestyle intervention (23), while another showed decreased intake at the end of treatment (22). Alcohol intake was not related to weight change but was associated with change in end-of-treatment energy intake (22). Research is needed to assess changes in alcohol consumption during weight loss and the effect of alcohol on weight management.

The present study used data from the Action for Health in Diabetes (Look AHEAD) study to address these questions. Look AHEAD is a 16-center randomized clinical trial that compared the effects of an intensive lifestyle intervention (ILI) to a diabetes support and education (DSE) control group on the incidence of major cardiovascular events (24). The aims of this study were to (1) assess the effect of the ILI on alcohol consumption over 4 years and (2) examine whether 4-year weight-loss outcomes were related to alcohol consumption over this time. We hypothesized that the ILI, as compared with the DSE, would have greater declines in alcohol consumption from baseline to year 4. We also hypothesized that in the ILI, individuals who reported greater alcohol consumption would lose less weight than those with lower alcohol consumption over the 4 years.

Methods

Participants

As reported previously, 5,145 participants were recruited from across the United States for the Look AHEAD study (25). Individuals had type 2 diabetes, were 45 to 76 years of age, and had BMI 25 kg/m² (or ≥27 kg/m² if on insulin). The current study used the Look AHEAD public access data set, a subset of 4,901 participants from the cohort; participants from the Native American sites were not included because of consent limitations.

Interventions

Details about the study interventions have been published previously (26). In brief, participants were randomly assigned to ILI or DSE (26,27). The ILI consisted of individual and group sessions focused on improving diet and physical activity. Participants were prescribed a calorie goal of 1,200 to 1,800 kcal/d (based on weight) and a physical activity goal of ≥175 min/wk of moderate-intensity activity. The ILI group was told about the number of calories in alcohol, advised to decrease alcohol consumption as a means of reducing caloric intake, and told that dietary guidelines recommended no more than two drinks per day for men and no more than one drink per day for women. Participants in the DSE group were invited to three group sessions each year focused on diet, physical activity, or social support.

Assessments

Assessments were completed by certified staff members masked to intervention assignment.

Demographic and clinical characteristics. Self-report forms were used to collect demographic and health data. Weight and height were measured in duplicate following standardized procedures (25). Glycated hemoglobin level was measured annually.

Alcohol. Alcohol consumption was assessed yearly using a self-report questionnaire that asked similar questions as those recommended by the National Institute on Alcohol Abuse and Alcoholism (28). Participants were asked, “Did you drink any alcoholic beverages in the past year?” as well as follow-up questions to assess the number of drinks of wine, beer, and liquor typically consumed each week. One drink was considered a 5-ounce glass of wine, 12-ounce glass, can, or bottle of beer, or 1.5 ounces of liquor. Responses were totaled to generate a score for number of drinks per week.

Dietary intake. Dietary intake was measured on 50% of participants at each clinical site using a self-administered 134-line item food frequency questionnaire that assessed typical consumption during the past 6 months. Calories from alcohol were computed based on g/d of alcohol consumed multiplied by 7.1 kcal/g.

Physical activity. Physical activity was assessed using the Paffenbarger Activity Questionnaire (29), which provides an estimate of weekly energy expenditure from moderate-intensity physical activity. Participants at eight centers completed the questionnaire at baseline and years 1 and 4.

Depressive symptoms and quality of life. The Beck Depression Inventory was used to assess depressive symptoms over the previous 2 weeks (30). The 36-item Short-Form Health Survey was used to assess physical and mental health-related quality of life (31).

Definition of alcohol groups

Baseline. The National Institute on Alcohol Abuse and Alcoholism’s drinking categories guided classification of baseline alcohol intake, based on the average quantity of alcohol consumed per week (28). Categories were (1) nondrinkers (no drinking at baseline), (2) light drinking (< 7 drinks/week for men and < 4 drinks/week for women), (3) moderate drinking (7-14 drinks/week for men and 4-7 drinks/week for women), and (4) heavy drinking (> 14 drinks/week for men and > 7 drinks/week for women).

Year 1. To describe longitudinal drinking patterns at 1 year, we created categories based on the baseline and year-1 reports of drinking in the past year (yes/no) and the average quantity of alcohol consumed per week. The groups were (1) those who were abstinent at both times, (2) participants who drank at baseline only, (3) those who endorsed drinking at year 1 only, (4) individuals who drank at both baseline and year 1 averaging to a light amount (< 7 drinks/week for men and < 4 drinks/week for women), (5) those who drank at both times averaging to a moderate
amount (7-14 drinks/week for men and 4-7 drinks/week for women), and (6) participants who drank at both times averaging to a heavy amount (> 14 drinks/week for men and > 7 drinks/week for women).

Year 4. At year 4, groups were formed in a similar manner as in year 1. The groups were (1) those who were abstinent at every survey (abstainers), (2) those who reported drinking at some years between baseline to 4 years (inconsistent drinkers), (3) those who drank at every year they were surveyed, averaging to a light amount (consistent light drinkers), (4) those who reported drinking at every year surveyed, averaging to a moderate amount (consistent moderate drinkers), and (5) those who drank at every year surveyed, averaging to a heavy amount (consistent heavy drinkers). To be included, participants had to complete the alcohol survey at three or more time points.

Statistical analyses
Baseline characteristics were compared by baseline alcohol group using analysis of variance (ANOVA) and χ² tests. We estimated the effect of the ILI (vs. DSE) on total alcohol consumption using linear mixed models, with the change from baseline to year 4 in drinks consumed per week as the main outcome. Models were estimated including all participants and repeated including only participants who endorsed drinking alcohol at baseline. We conducted post hoc analyses examining changes from baseline to year 1, changes in wine, beer, and liquor consumption, and changes based on baseline alcohol consumption and year-4 alcohol consumption groups. We tested an interaction term for gender and change in alcohol consumption and repeated analyses stratified by gender.

The coprimary outcome compared 4-year percent change in baseline weight based on the trajectory of alcohol consumption across 4 years. Models were analyzed stratified by treatment using a piecewise, linear mixed-effects model with a breakpoint at year 1. Models were adjusted for baseline demographic and clinical differences among alcohol consumption groups. Similar analyses were conducted to examine changes during the first year, when the intervention was most intensive and weight losses were the largest, using the year-1 alcohol groups. Participants were compared based on alcohol trajectory and categorical weight losses at year 4 (e.g., ≥ 10% loss) using χ² tests. Exploratory analyses were conducted to estimate changes in self-reported dietary intake and physical activity based on 4-year alcohol trajectory. Analyses were performed using SPSS Statistics software version 25 (IBM Corp., Armonk, New York) with a type I error rate of 0.05.

Results
Baseline differences based on baseline alcohol consumption
At baseline, 38.1% of the cohort reported not drinking alcohol in the past year, 53.8% reported light drinking, 6.3% reported moderate drinking, and 1.7% reported heavy drinking. Characteristics of participants by baseline alcohol consumption are presented in Table 1.

Alcohol consumption by treatment group
At year 4, weight data were obtained on 90.1% of the sample, and both weight and alcohol data were available for 88.6% of participants. Individuals who were moderate drinkers at baseline were more likely to complete the full 4-year assessment (weight and questionnaire data) than those in the other alcohol categories (92.9% vs. 87.5% for never drinkers, 88.8% for light drinkers, 90.2% for heavy drinkers; P = 0.04).

The ILI and DSE groups did not differ by baseline alcohol consumption categorization (P = 0.61). ILI and DSE participants did not differ significantly in changes from baseline to year 1 or from baseline to year 4 in total alcohol consumption or wine, beer, and liquor consumed (P > 0.05; Table 2). ILI and DSE groups did not differ in alcohol consumption (P > 0.05) when restricted to participants who drank alcohol at baseline or when stratified by baseline alcohol group (P > 0.05; Supporting Information Table S1) or by year-4 alcohol consumption group (P > 0.05; Supporting Information Table S1). Gender did not significantly interact with treatment group and change in consumption of total alcohol (P = 0.60), wine (P = 0.27; Supporting Information Table S2), beer (P = 0.45), or liquor (P = 0.54) at year 4. Statistical conclusions were the same at year 1.

Groups at year 1. In the ILI and DSE groups, similar percentages of participants were classified as abstinent from alcohol at baseline and year 1 (39.5% vs. 40.5%, respectively), baseline only (12.0% vs. 11.0%), and year 1 only (5.1% vs. 4.3%). The groups did not differ significantly (P = 0.67) in the percentage of people who drank at both times who were classified as light drinkers (34.6% vs. 34.5%), moderate drinkers (6.8% vs. 7.4%), and heavy drinkers (2.0% vs. 2.3%).

Groups at year 4. From baseline to 4 years, ILI participants reported drinking alcohol at a mean ± standard deviation (SD) of 2.7 ± 2.1 annual assessments, which did not differ (P = 0.64) from the 2.7 ± 2.2 time points reported by DSE participants. Randomization arm did not have a main effect on alcohol trajectory (P = 0.16). A similar percentage of participants reported abstaining from alcohol at all annual assessments in the ILI (29.4%) and DSE groups (31.4%). ILI and DSE participants did not differ in the percentage of participants who endorsed inconsistent drinking (35.7% vs. 32.1%, respectively) or those who reported consistent drinking at a light (28.4% vs. 29.4%), moderate (4.6% vs. 5.2%), or heavy amount (1.9% vs. 2.0%).

ILI
Weight. In the ILI group, alcohol consumption trajectory did not have a main effect on weight loss at year 1 (P > 0.05; Figure 1). ILI participants who abstained from alcohol lost a mean ± standard error (SE) of 8.9% ± 0.3% of initial weight at year 1, which did not differ significantly (P = 0.99) from the 9.1% ± 1.2% lost by participants who drank a heavy amount. Participants who drank only at baseline lost 9.1% ± 0.5%, and those who drank only at year 1 lost 8.2% ± 0.7%. Relative to participants who were abstinent from alcohol, participants who drank at baseline and year 1 lost a similar amount regardless of whether they drank a light (8.9% ± 0.3%, P = 0.29), moderate (9.7% ± 0.7%, P = 0.40), or heavy amount (P = 0.99).

At year 4, ILI participants who abstained from alcohol consumption over the 4 years lost 1.6% ± 0.5% more weight compared with individuals who drank alcohol at any time over the 4 years (P = 0.003). ILI participants who abstained from alcohol (over the 4 years) lost 5.1% ± 0.3% of initial weight at year 4 compared with the significantly (P = 0.04) smaller loss of 2.4% ± 1.3% for participants who were consistent heavy drinkers (Figure 2). The weight losses of participants...
who were abstinent from alcohol were significantly larger than the 3.8% ± 0.3% losses of participants who drank inconsistently (P = 0.01) and 4.2% ± 0.4% losses of those who were consistent light drinkers (P = 0.047). Participants who were consistent moderate drinkers lost 3.7% ± 0.9%. Weight loss for consistent heavy drinkers was not significantly different compared with those who were inconsistent (P = 0.28), consistent light (P = 0.19), or consistent moderate drinkers (P = 0.40).

At year 4, meeting a categorical weight loss of ≥10% differed by alcohol trajectory group (P = 0.002; Figure 3A). The percentage of participants who achieved ≥10% weight loss was significantly higher than expected in the abstainer group (27.5%). In the consistent heavy drinker group only two participants achieved ≥10% weight loss (4.8%). The percentages of participants who achieved this weight loss were 22.6% of inconsistent drinkers, 22.9% of consistent light drinkers, and 16.0% of consistent moderate drinkers.

### TABLE 1 Demographic and clinical characteristics by baseline alcohol use

|                         | None        | Light       | Moderate    | Heavy       | P value |
|-------------------------|-------------|-------------|-------------|-------------|---------|

Values shown are the mean±error for number of drinks per week.

Figure 1: Percent weight change at year 1 by the following alcohol groups: abstinent, baseline only, year 1 only, individuals who drank at both baseline and year 1 averaging to a light amount (<7 drinks/week for men and <4 drinks/week for women), those who drank at both times averaging to a moderate amount (7-14 drinks/week for men and 4-7 drinks/week for women), and participants who drank at both times averaging to a heavy amount (>14 drinks/week for men and >7 drinks/week for women). DSE, diabetes support and education; ILI, intensive lifestyle intervention.
of consistent moderate drinkers. Categorical weight losses differed by alcohol consumption trajectory for the achievement of a ≥ 5% \( (P=0.01) \) loss of initial weight. The alcohol abstainer group had 52.4% of participants who met a 5% weight loss compared with 44% of inconsistent drinkers, 44% of consistent light drinkers, 41% of consistent moderate drinkers, and 33.3% of consistent heavy drinkers.

**Diet.** In exploratory analyses with the subgroup of participants with data from the food frequency questionnaire, each alcohol trajectory group had significant within-group declines in dietary calories from baseline to year 1 and baseline to year 4 \( (P<0.05;\ Figure \ 4A) \). Change in dietary intake did not differ by alcohol trajectory group \( (P>0.05) \). At year 4, relative to those who were abstinent from alcohol, inconsistent drinkers reported an additional mean±SE of 28.8±50.4 kcal/d \( (P=0.57) \), consistent light drinkers 182.8±51.9 kcal/d \( (P<0.001) \), consistent moderate drinkers 188.9±110.0 kcal/d \( (P=0.09) \), and consistent heavy drinkers 79.4±4.0 kcal/d \( (P=0.59) \). At year 4, the average reported kilocalories per day of alcohol ingested was 4.7±1.4 by inconsistent drinkers, 21.5±1.4 by consistent light drinkers, 79.4±4.0 by consistent moderate drinkers, and 139.5±5.7 by consistent heavy drinkers.

**Physical activity.** In the subgroup of participants who completed the Paffenbarger Activity Questionnaire, changes in physical activity from baseline to year 1 were significant for each group \( (P<0.05;\ Figure \ 5A) \). Baseline to year-4 improvements in physical activity were significant for all groups except consistent heavy drinkers \( (P=0.54) \). Changes in baseline to year-4 physical activity did not differ significantly \( (P>0.05) \) between those who abstained from alcohol and all other groups. At year 4, the amount of physical activity reported by each of the alcohol trajectory groups did not differ \( (P>0.05) \).

**DSE**

**Weight.** In the DSE group, participants who were abstinent from alcohol over the first year had similar weight changes as those who drank alcohol during the first year \( (P=0.19) \). Abstinent individuals in the DSE group lost 0.5%±0.2% of initial body weight, while participants who drank at baseline lost only 0.7%±0.3% \( (P=0.60) \), and those who drank at year 1 lost only 0.7%±0.6% \( (P=0.75;\ Figure \ 1) \). Compared with abstinent drinkers, light drinkers lost 1.1%±0.2% \( (P=0.002) \), moderate drinkers lost 1.1%±0.4% \( (P=0.05) \), and heavy drinkers lost 0.3%±0.8% \( (P=0.75) \).

At year 4, participants in the DSE group who did not report drinking at any time lost 1.5%±0.3% of initial weight, which was similar to the amount lost by individuals who drank at any time \( (P=0.48) \). Percent weight loss for participants who were abstinent was not significantly different from individuals in DSE who reported inconsistent \((0.9%±0.3%;\ P=0.19)\), light \(1.5%±0.4%;\ P=0.96)\), moderate \(1.3%±0.9%;\ P=0.81)\), or heavy drinking \(0.8%±1.4%;\ P=0.62)\) (Figure 6). At year 4, the groups did not differ \(P=0.47\) in the percentage of participants who met a ≥10% weight loss. The percentages of participants who met this goal were 12.1% of abstainers, 10.8% of inconsistent drinkers, 9.8% of consistent light drinkers, 7.1% of consistent moderate drinkers, and 11.9% of consistent heavy drinkers (Figure 3B). Categorical percent weight losses did not differ by alcohol trajectory at ≥ 5% \(P=0.82\).

**Diet.** At year 4, relative to DSE participants who were abstinent from alcohol, inconsistent drinkers consumed 125.4±57.4 kcal/d more \( (P=0.03;\ Figure \ 4B) \), consistent light drinkers 190.0±58.2 kcal/d more \( (P=0.001) \), consistent moderate drinkers 373.4±105.8 kcal/d more \(P<0.001)\), and consistent heavy drinkers 190.4±163.5 kcal/d.
more \((P=0.25)\). Individuals who were inconsistent drinkers reported an average of \(5.7 \pm 1.3\) kcal/d from alcohol, consistent light drinkers \(18.8 \pm 1.3\) kcal/d, consistent moderate drinkers \(71.4 \pm 3.1\) kcal/d, and consistent heavy drinkers \(137.8 \pm 5.0\) kcal/d.

**Physical activity.** Consistent light drinkers had significant changes in physical activity from baseline to year 1 and baseline to year 4 \((P=0.001, 0.02; \text{Figure 5B})\). Change in physical activity from baseline to year 1 and baseline to year 4 did not differ significantly by alcohol trajectory group \((P>0.05)\).

**Discussion**

Among adults with overweight or obesity and type 2 diabetes, changes in alcohol consumption from baseline to year 1 and baseline to year 4 did not differ between participants enrolled in the ILI versus DSE. Alcohol consumption was not related to year-1 weight loss among those randomized to the ILI. However, alcohol consumption was associated with weight loss achieved at year 4, suggesting that alcohol may have different physiological or behavioral implications for short- versus long-term weight loss. ILI participants who abstained from alcohol
over the 4 years lost 5.1% of initial weight at year 4 compared with the significantly smaller loss of 2.4% for participants who were consistent heavy drinkers. Compared with individuals who abstained from alcohol over the 4 years, consistent heavy drinkers were less likely to have clinically significant weight losses of ≥ 5% and ≥ 10% at year 4. There is consistent evidence that chronic heavy drinking is associated with negative health outcomes, including liver cirrhosis, chronic pancreatitis, cancer, and cardiovascular disease (32,33). This study indicates that heavy drinking attenuates long-term weight loss among adults with type 2 diabetes.

Weight losses between participants who did and did not abstain from alcohol were similar during the first year of the program. However, at year 4, participants in the ILI who abstained from alcohol lost 1.6% more weight relative to individuals who drank alcohol at any time over the 4 years. Our exploratory analyses of the subgroups of participants who completed the food frequency and physical activity questionnaires demonstrated that changes in dietary intake and physical activity were not significantly different among alcohol trajectory groups. However, at year 4, calories from alcohol partially, but not completely, explained differences in caloric intake between abstainers and inconsistent drinkers.

Figure 4 Mean self-reported daily caloric intake at baseline and years 1 and 4 based on 4-year alcohol trajectory in the (A) intensive lifestyle intervention (ILI) and (B) diabetes support and education (DSE) groups. Error bars represent the standard error. Grey bars represent nonalcoholic dietary intake. Black bars represent calories from alcohol. *P < 0.05 for difference relative to abstinent group in total dietary intake value at baseline, year 1, or year 4. &P < 0.05 for differences relative to abstinent group in nonalcohol dietary intake. The amount of change in total dietary intake from baseline to year 1 and baseline to year 4 did not differ significantly by alcohol trajectory group (P > 0.05). ILI: each alcohol trajectory group had significant within-group declines in dietary intake from baseline to year 1 and baseline to year 4 (P < 0.05). DSE: each group had significant declines in dietary intake from baseline to year 1 with the exception of the consistent-moderate group, which was not significant for either.
consistent light drinkers, and consistent moderate drinkers. Thus, alcohol added calories to daily energy intake, and participants may have been less adherent to calorie goals, leading to less weight loss. For ILI participants who were consistent heavy drinkers, the additional calories reported from alcohol accounted for all of the extra dietary calories relative to participants who were abstinent from alcohol. We believe that participants who drank alcohol may have compensated for calories from alcohol during the short term (i.e., by decreasing their calorie intake from food) but had more difficulties in the long term when weight typically plateaus and biological and behavioral factors may make it more difficult to maintain weight loss (34). The results also support previous research that individuals often do not decrease subsequent intake to account for the calories consumed from alcohol (10,35,36). Alcohol consumption before or with a meal can stimulate food intake (7,10), which may have resulted in overeating. Participants with consistent heavy alcohol consumption had significant improvements in physical activity from baseline to year 1 \( (P=0.001) \) and baseline to year 4 \( (P=0.02) \). Compared with abstainers, the other groups did not differ significantly in change in physical activity \( (P>0.05) \).

**Figure 5** Mean self-reported kilocalories of physical activity per week at baseline and years 1 and 4 based on 4-year alcohol trajectory in the (A) intensive lifestyle intervention (ILI) and (B) diabetes support and education (DSE) groups. ILI: each alcohol trajectory group had significant within-group improvement in physical activity from baseline to year 1. Baseline to year-4 changes in physical activity were significant within group for all except consistent heavy drinkers \( (P=0.54) \). Changes in baseline to year-4 physical activity did not differ significantly \( (P>0.05) \) between those who abstained from alcohol and all other groups. DSE: consistent light drinkers had significant improvement in physical activity from baseline to year 1 \( (P=0.001) \) and baseline to year 4 \( (P=0.02) \). Compared with abstainers, the other groups did not differ significantly in change in physical activity \( (P>0.05) \).
mediators underlying the effects of alcohol on weight-loss efforts, such as impulsivity, food choices, and physical activity.

These results indicate that abstaining from alcohol offers some modest benefits for long-term weight control. However, the clinical significance of this difference is uncertain, and results should be taken in context of the potential (though controversial) benefits of light to moderate alcohol consumption. There is a “J” or “U” shaped relationship between alcohol consumption and some health outcomes. For example, light to moderate alcohol intake is associated with a lower risk of cardiovascular disease relative to people who are never drinkers or those who are heavy drinkers (38,39). For other conditions, such as breast cancer, there is no known safe level of alcohol consumption (40). The U.S. Dietary Guidelines for Americans indicate that if alcohol is consumed, it should be consumed in moderation (i.e., one drink per day for women and up to two drinks per day for men) (41). Studies are needed to assess whether the benefits of light to moderate alcohol consumption on cardiovascular disease may outweigh the risks of worse weight loss.

Alcohol consumption was not associated with weight in the DSE group, suggesting that the effects of alcohol on weight may be more evident during ILI (and weight loss) versus control conditions (when weight is relatively stable). These differences may be explained by diet, physical activity, or other factors that differed between the ILI and DSE groups. Research is needed to assess differences in the effect of alcohol on weight loss versus weight-gain prevention.

Contrary to previous reports of declines in alcohol consumption during behavioral obesity treatment (22), we found that individuals in the ILI did not decrease their alcohol intake more than those in the DSE. Participants in the ILI were advised to decrease alcohol consumption but not instructed to completely eliminate alcohol, which may account for the null findings. There may have been floor effects that reduced our ability to detect differences between groups. At baseline, 61.8% of participants reported consuming alcohol in the past year, which is slightly less than the 70% of Americans from the general population (2,3). The overall quantity of alcohol consumed was low, consistent with previous findings that heavier drinking is less common among older adults compared with younger adults as well as those with diabetes relative to the general population (42). Further replication in younger samples and in people without diabetes is warranted.

Strengths of this study include the large sample size, longer-term follow-up, and excellent retention rate. We adjusted for several confounders, though unmeasured and residual confounders could have influenced findings, such as drinking history, ill health, diseases or their treatment that may have prevented alcohol use, or psychosocial factors. We did not adjust for dietary intake or physical activity in models because only 27.3% of participants completed both measures. This study has several other limitations. Alcohol consumption, dietary intake, and physical activity were self-reported, which may have led to underreporting of calories consumed and overreporting of physical activity. The time frame used for alcohol was 1 year, which helped capture infrequent drinkers and seasonal variations in alcohol habits but may have resulted in recall bias (43). Data on daily alcohol consumption were not available, and thus a weekly amount was used. Participants had type 2 diabetes, and the overall depression severity was low, which limit generalizability of findings. The number of participants with heavy alcohol consumption was low, resulting in large confidence intervals within this group. While gender was included as a covariate, further studies are needed to examine the interactions among gender, alcohol consumption, and weight loss.
In conclusion, our findings suggest that while alcohol consumption is not associated with short-term weight loss during a lifestyle intervention, it is associated with worse long-term weight loss in participants with overweight or obesity and type 2 diabetes. Participants who drank alcohol at any time over the 4 years lost less weight relative to participants who did not drink at any time. Participants who were consistent heavy alcohol drinkers were at greatest risk for suboptimal long-term weight losses. Participants with type 2 diabetes who are trying to lose weight should be encouraged to reduce alcohol consumption. Though weight loss was greater among those who abstained from alcohol, further research is needed to assess the potential beneficial (e.g., cardiovascular disease, mortality) and detrimental effects of light to moderate alcohol consumption on individuals trying to lose weight. Ultimately, randomized controlled trials are necessary to test whether eliminating alcohol consumption improves weight loss and other cardiovascular outcomes during lifestyle interventions.
