We study the problem of estimating the Earth Mover’s Distance (EMD) between probability distributions when given access only to samples. We give closeness testers and additive-error estimators over domains in $[0, \Delta]^d$, with sample complexities independent of domain size – permitting the testability even of continuous distributions over infinite domains. Instead, our algorithms depend on other parameters, such as the diameter of the domain space, which may be significantly smaller. We also prove lower bounds showing the dependencies on these parameters to be essentially optimal. Additionally, we consider whether natural classes of distributions exist for which there are algorithms with better dependence on the dimension, and show that for highly clusterable data, this is indeed the case. Lastly, we consider a variant of the EMD, defined over tree metrics instead of the usual $\ell_1$ metric, and give optimal algorithms.

1 Introduction

In traditional algorithmic settings, algorithms requiring linear time and/or space are generally considered to be highly efficient; sometimes even polynomial time and space requirements are acceptable. However, today this is often no longer the case. With data being generated at rates of terabytes a second, sublinear time algorithms have become crucial in many applications. In the increasingly important area of massive data algorithms, a number of models have been proposed and studied to address this. One of these arises when the data can be naturally viewed as a probability distribution (e.g., over IP addresses, or items sold by an online retailer, etc.) that allows i.i.d. samples to be drawn from it. This is the model on which this paper focuses.

Perhaps the most fundamental problem in this model is that of testing whether two distributions are close. For instance, if an online retailer such as Amazon.com wishes to detect changes in consumer habits, one way of doing so might be to see if the distribution of sales over all offered items this week, say, is significantly different from last week’s distribution. This problem has been studied extensively, mostly under the $\ell_1$ and $\ell_2$ distances, and algorithms sublinear in time and sample complexity exist to distinguish whether two distributions are identical or $\varepsilon$-far from each other [4, 7, 18]. However, under the $\ell_1$ distance, for instance, the sample complexity, though sublinear, can be no smaller than $n^{2/3}$ (where $n$ is the domain size), which may be prohibitively large [4, 18].

Fortunately, in many situations there is a natural metric on the underlying domain, under which nearby points should be treated as “less different” than faraway points. This motivates a metric known as Earth Mover’s Distance (EMD), first introduced in the vision community as a
measure of (dis)similarity between images that more accurately reflects human perception than more traditional $\ell_1$ [11]. It has since proven to be important in computer graphics and vision [13, 12, 14, 6, 16, 17, 15], and has natural applications to other areas of computer science. As a result, its computational aspects have recently drawn attention from the algorithms community as well [2, 9, 5, 8]. However, previous work has generally focused on the more classical model of approximating the EMD when given the input distributions explicitly; that is, when the exact probability of any domain element can be queried. As far as we know, no work has been done on estimating and closeness testing of EMD when given access only to i.i.d. samples of the distributions.

In this model, it is easy to see that we cannot hope to compute a multiplicative approximation, even with arbitrarily many samples, since that would require us to distinguish between arbitrarily close distributions and identical ones. However, if we settle for additive error, we show in this paper that, in contrast to the $\ell_1$ distance, we can estimate EMD using a number of samples independent of the domain size. Instead, our sample complexities depend only on the diameter of the domain space, which in many cases can be significantly smaller. The consequence is that this allows us to effectively deal with distributions over extremely large domains, and even, under a natural generalization of EMD, continuous distributions over infinite domains.

Specifically, if $p$ and $q$ are distributions over $M \subset [0, \Delta]^d$ (where $d$ is a constant), we can

- estimate $EMD(p, q)$ to within an additive error of $\varepsilon$ with $\tilde{O}((\Delta/\varepsilon)^d + O(1))$ samples,
- distinguish whether $p = q$ or $EMD(p, q) > \varepsilon$ with $\tilde{O}((\Delta/\varepsilon)^{2d/3+O(1)})$ samples, and
- if $q$ is known, distinguish whether $p = q$ or $EMD(p, q) > \varepsilon$ with $\tilde{O}((\Delta/\varepsilon)^{d/2+O(1)})$ samples.

We also give lower bounds that imply these results to be essentially optimal (up to small poly$(\Delta/\varepsilon)$ factors). In the case of $d = 1$ or 2, upper and lower bounds for both testers become $\Theta((\Delta/\varepsilon)^2)$.

Additionally, we consider assumptions on the data that might make the problem easier, and give an improved algorithm in the case our input distributions is highly clusterable. Finally, it is natural to consider the EMD over domains endowed with a metric other than $\ell_1$ distance. We give an optimal (upto polylogarithmic factors) algorithm for estimating EMD over tree metrics.

2 Preliminaries

2.1 Earth Mover’s Distance

We start with the following definition.

**Definition 1** A supply-demand network is a directed bipartite graph $G = (S \cup T, E)$ consisting of supply vertices $S$ and demand vertices $T$, with supply distribution $p$ on $S$ and demand distribution $q$ on $T$, and edge set $E = S \times T$, with associated weights $w : E \rightarrow \mathbb{R}^+$. A satisfying
flow for \( G \) is a mapping \( f : E \rightarrow \mathbb{R}^+ \) such that for each \( s \in S \) and each \( t \in T \),

\[
\sum_{t' \in T} f((s, t')) = p(s), \quad \text{and} \quad \sum_{s' \in S} f((s', t)) = q(t).
\]

The cost of satisfying flow \( f \) is given by

\[
C(f) = \sum_{e \in E} f(e)w(e).
\]

We define the Earth Mover’s Distance (EMD) as follows.

**Definition 2** Let \( p \) and \( q \) be probability distributions on a finite metric space \((M, \delta)\). Then let \( G \) be the supply-demand network given by supply vertices \( S = \{s_x \mid x \in M\} \) and demand vertices \( T = \{t_x \mid x \in M\} \), with supply distribution \( \hat{p} : s_x \mapsto p(x) \) and demand distribution \( \hat{q} : t_x \mapsto q(x) \), and edge weights \( w : (s_x, t_y) \mapsto \delta(x, y) \). Define \( \text{EMD}(p, q) \) to be the minimum cost of all satisfying flows for \( G \).

It is straightforward to verify that the EMD as defined above is a metric on all probability distributions on \( M \). Note, moreover, that to upperbound the EMD it suffices to exhibit any satisfying flow.

Since the magnitude of the EMD depends on the distances in the underlying metric space \( M \), we must assume that \( M \) is of bounded diameter. In particular, we will in this paper focus mostly on the case where \( M \subset [0, \Delta]^d \), for some \( \Delta > 0 \), endowed with the \( \ell_1 \) metric.

Finally, we define a closeness tester for the EMD in the usual way as follows.

**Definition 3** Let \( p, q \) be two distributions on (finite) metric space \( M \). An EMD-closeness tester is an algorithm which takes as input samples from \( p \) and \( q \), together with a real number \( \varepsilon > 0 \), and guarantees that

1. if \( p = q \), then it accepts with probability at least \( 2/3 \), and
2. if \( \text{EMD}(p, q) > \varepsilon \), then it rejects with probability at least \( 2/3 \).

Note that it is also possible to define EMD for any two probability measures \( p \) and \( q \) in an infinite (continuous) metric space \((\mathcal{M}, \delta_M)\), \( \mathcal{M} \subset [0, \Delta]^d \), by using Wasserstein metric:

\[
\text{EMD}(p, q) = \inf_{\gamma \in \Gamma(p, q)} \int_{\mathcal{M} \times \mathcal{M}} \delta_M(x, y)d\gamma(x, y)
\]

where \( \Gamma(p, q) \) denotes the collection of all measures on \( \mathcal{M} \times \mathcal{M} \) with marginals \( p \) and \( q \) on the first and second factors respectively. By using \( \varepsilon/4\)-net, \((\mathcal{M}, \delta_M)\) can be discretized into a finite metric \((M, \delta)\) in such a way that the EMD distance of any two probability measures only increases or decreases at most \( \varepsilon/2 \). Therefore, an EMD-closeness tester with additive error \( \varepsilon/2 \) for \((M, \delta)\) is also a valid EMD-closeness tester for \((\mathcal{M}, \delta)\) with additive error \( \varepsilon \).
2.2 Properties of EMD

Let us get a firmer handle on the EMD by relating it to $\ell_1$ distance, via the following lemmas.

**Lemma 4** If $p$ and $q$ are distributions on $(M, \delta)$, there exists a minimum cost satisfying flow $f$ from $S$ to $T$ (as defined in Def. 2) such that the total amount sent by $f$ across edges with non-zero cost is exactly $||p - q||_1/2$.

**Proof** Let $a = \sum_x \min\{p(x), q(x)\}$ and $A = \sum_x \max\{p(x), q(x)\}$, so that $A - a = ||p - q||_1$ and $A + a = 2$. Observe that the total amount sent from $S$ to $T$ is 1, and the maximum possible amount sent across edges with zero cost is $a$, which leaves at least $1 - a = ||p - q||_1/2$ to be sent across non-zero cost edges.

On the other hand, suppose that for some $x$, an optimal flow through the edge $(s_x, t_x)$ is less than $\min\{p(x), q(x)\}$. Then there exist points $y$ and $z$ such that $f$ sends at least $\alpha > 0$ from $s_x$ to $t_y$ and from $s_z$ to $t_x$. We can replace this partial flow, which costs $\alpha(\delta(x, y) + \delta(x, z))$, with one sending $\alpha$ from $s_x$ to $t_x$ and from $s_z$ to $t_y$, which costs $\alpha(\delta(y, z))$. Doing so, we will not increase the total cost (by triangle inequality), nor will we affect the rest of the flow. We can therefore repeated the procedure until we obtain an optimal flow that saturates every zero-edge.

**Corollary 5** If $p$ and $q$ are distributions on $M$, where $M$ has minimum distance $\delta$ and diameter $\Delta$, then

$$\frac{||p - q||_1}{2} \cdot \delta \leq EMD(p, q) \leq \frac{||p - q||_1}{2} \cdot \Delta.$$ 

**Lemma 6** Let $p$ and $q$ be distributions on $M$ with diameter $\Delta$, and $M = \{M_1, \ldots, M_k\}$ be a partition of $M$ wherein $\text{diam}(M_i) \leq \Gamma$ for every $i \in [k]$. Let $P$ and $Q$ be distributions on $M$ induced by $p$ and $q$, resp. Then $EMD(p, q) \leq \frac{||P - Q||_1}{2} \cdot \Delta + \Gamma$.

**Proof** Let us define distribution $p'$ by moving some of the probability weight of $p$ between $M_i$'s (taking from and depositing anywhere within the respective $M_i$'s) in such a way that $p'$ induces $Q$ on $M$. This is effectively a flow from $P$ to $Q$ where all distances are bounded by $\Delta$, so by Lemma 4, it can be done at cost at most $\frac{||P - Q||_1}{2} \cdot \Delta$. It follows that $EMD(p, p') \leq \frac{||P - Q||_1}{2} \cdot \Delta$.

Then, having equalized the probability weights of each $M_i$, let us move the probability weight of $p'$ within each $M_i$ to precisely match $q$. This might require moving everything (i.e., 1), but the distance anything is moved is at most $\Gamma$, so $EMD(p', q) \leq \Gamma$ and the lemma follows by triangle inequality.

2.3 Some tools from previous work

Here, for completeness, we state some results from previous work that we will make use of later. First, we define some useful distributions described in [9] for testing closeness between distributions over subsets of $[0, \Delta]^d$. 

4
Definition 7 Given distribution $p$ over $M \subset [0, \Delta]^d$ and a positive integer $i$, let $G^{(i)}$ be a grid with side length $\Delta^{2i}$ over $[0, \Delta]^d$ centered at the origin. Define the $i$-coarsening of $p$, denoted $p^{(i)}$, to be the distribution over the grid cells of $G^{(i)}$ such that, for each grid cell $c$ of $G^{(i)}$, $p^{(i)}(c) = \sum_{u \in c} p(u)$.

The $p^{(i)}$'s can be thought of as coarse approximations of $p$ where all points in the same grid cell are considered to be the same point. We then have the following lemma from [9] relating the EMD of two distributions to a weighted sum of the $\ell_1$ distances of their $i$-coarsenings.

Lemma 8 For any two distributions $p$ and $q$ over $M \subset [0, \Delta]^d$,

$$EMD(p, q) \leq d \left( \log \left( \frac{2\Delta^d}{\varepsilon} \right) \sum_{i=1}^{2^{i-1}} \frac{\Delta}{2^{i-1}} \cdot \|p^{(i)} - q^{(i)}\|_1 \right) + \frac{\varepsilon}{2}.$$

Having established the various relationships between the EMD and the $\ell_1$ distance, we will make use of the result from [4] below for testing closeness of distributions in $\ell_1$ as a subroutine.

Theorem 9 Given access to samples from two distributions $p$ and $q$ over $M$, where $|M| = n$, there exists an algorithm that takes $O\left( \frac{n^{2/3} \varepsilon^{4} \log n \log(1/\delta)}{\varepsilon^2} \right)$ samples and (1) accepts with probability at least $1 - \delta$ if $p = q$ and (2) rejects with probability at least $1 - \delta$ if $\|p - q\|_1 > \varepsilon$.

Alternatively, via a simple Chernoff bound analysis similar to [3], we can show that a whole distribution can be approximated efficiently, giving us another closeness tester for $\ell_1$.

Lemma 10 Given access to samples from a distribution $p$ over $M$, where $|M| = n$, and parameters $\varepsilon, \delta, t > 0$, there exists an algorithm that takes $O\left( \frac{t^{-1} \varepsilon^{-2} \log n \log(1/\delta)}{\varepsilon^2} \right)$ samples and outputs a distribution $\tilde{p}$ over $M$ such that with probability at least $1 - \delta$

$$(1 - \varepsilon) \max\{p(i), t\} \leq \tilde{p}(i) \leq (1 + \varepsilon) \max\{p(i), t\}$$

for every $i \in M$.

As a result, we can simply estimate $p$ and $q$ with $\tilde{p}$ and $\tilde{q}$, respectively, and compute their $\ell_1$ distance to get the following alternative tester, which gives us a different trade-off between $n$ and $\varepsilon$ that will become useful later.

Theorem 11 Given access to samples from two distributions $p$ and $q$ over $M$, where $|M| = n$, there exists an algorithm that takes $O\left( \frac{nc^{-2} \log n \log(1/\delta)}{\varepsilon^2} \right)$ samples and (1) accepts with probability at least $1 - \delta$ if $p = q$ and (2) rejects with probability at least $1 - \delta$ if $\|p - q\|_1 > \varepsilon$.

3 Closeness tester

In this section, we consider the EMD-closeness testing problem when the domain is $M \subset [0, \Delta]^d$. The main idea behind the algorithm is to embed EMD into the $\ell_1$ metric and use an $\ell_1$-closeness
tester (Theorems 9 and 11) to test the resulting distributions. Recall from the preliminaries, $p^{(i)}$ and $q^{(i)}$ are the $i$-coarsening approximations of $p$ and $q$. We have the following algorithm, where the subroutine $\ell_1$-Closeness-Tester($p, q, \varepsilon, \delta$) is an $\ell_1$-closeness tester on distributions $p$ and $q$ with distance parameter $\varepsilon$ and failure probability $\delta$.

**EMD-Closeness-Tester** ($p, q, \varepsilon$)

1. for $i = 1$ to $\log(2\Delta d/\varepsilon)$ do
2. if $\ell_1$-Closeness-Tester($p^{(i)}, q^{(i)}, \varepsilon^{2i-2}, \frac{1}{\Delta d \log(2\Delta d/\varepsilon)}$, $\frac{1}{3 \log(2\Delta d/\varepsilon)}$) rejects then
3. reject
4. accept

Note that our subroutine takes advantage of whichever tester (Theorem 9 or 11) requires fewer samples. Specifically, when $d$ is small, the domains of the $i$-coarsenings of $p$ and $q$ are small and $\varepsilon$ is the bottleneck, so we use Theorem 11. On the other hand, if $d$ is large, the sizes of these domains become the bottleneck and we use Theorem 9. This gives us the following theorem.

**Theorem 12** The above is an EMD-closeness tester for distributions over $M \subset [0, \Delta]^d$ that takes $\tilde{O}((2\Delta d/\varepsilon)^{2d/3})$ samples when $d \geq 6$ and $\tilde{O}((\Delta/\varepsilon)^2)$ samples when $d \leq 2$.

**Proof** If $p = q$, then $p^{(i)} = q^{(i)}$ for all $i$, so by the union bound, the probability that the algorithm rejects is at most $\log \frac{2\Delta d}{\varepsilon} \cdot \frac{1}{3 \log \frac{2\Delta d}{\varepsilon}} = \frac{1}{3}$.

If, on the other hand, $EMD(p, q) > \varepsilon$, then by Lemma 8

$$d \left( \sum_{i=1}^{\log(2\Delta d/\varepsilon)} \frac{\Delta}{2^{i-1}} \cdot \left\| p^{(i)} - q^{(i)} \right\|_1 \right) > \frac{\varepsilon}{2}.$$ 

It follows by the pigeonhole principle that there exists an index $i$ such that

$$\left\| p^{(i)} - q^{(i)} \right\|_1 > \frac{\varepsilon 2^{i-2}}{\Delta d \log(2\Delta d/\varepsilon)}.$$ 

Hence, for that index $i$, the $\ell_1$-closeness tester in Step 2 will reject (with probability 2/3).

Now let us analyze the number of samples the algorithm needs. In the $i^{th}$ iteration of the main loop, $p^{(i)}$ and $q^{(i)}$ has a domain with $n_i = 2^{di}$ elements, and we need to run an $\ell_1$-closeness tester with a distance parameter of $\varepsilon_i = \frac{\varepsilon 2^{i-2}}{\Delta d \log(2\Delta d/\varepsilon)}$. Consider the following two cases:

- $d \geq 6$: Using the algorithm of Theorem 9 we get a sample complexity of

$$\tilde{O}(n_i^{2/3} \frac{1}{\varepsilon_i})^4 = \tilde{O} \left( 2^{(2d/3 - 4)i} \left( \frac{4\Delta d \log(2\Delta d/\varepsilon)}{\varepsilon} \right)^4 \right).$$

This quantity is maximized when $i = \log(2\Delta d/\varepsilon)$, which gives us a total complexity of $\tilde{O}((2\Delta d/\varepsilon)^{2d/3})$.
• \( d \leq 2 \): Using the algorithm of Theorem 11, we get a sample complexity of

\[
\tilde{O}(n_i \varepsilon_i^{-2}) = \tilde{O} \left( 2^{(d-2)i} \left( \frac{4 \Delta d \log(2 \Delta d / \varepsilon)}{\varepsilon} \right)^2 \right).
\]

This quantity is maximized when \( i = 1 \), giving us a total complexity of \( \tilde{O}(\Delta / \varepsilon)^2 \).

If one of the distributions is explicitly known, we can use the corresponding \( \ell_1 \)-closeness tester with sample complexity \( O(n^{1/2} \varepsilon^{-2} \log n) \) from [3] to similarly get the following theorem.

**Theorem 13** There exists an EMD-closeness tester for distributions over \( M \subset [0, \Delta]^d \), where one is explicitly known, that takes \( \tilde{O}(2 \Delta / \varepsilon)^{d/2} \) samples when \( d \geq 4 \).

### 4 Additive-error estimation

We have seen that in \( \ell_1 \)-closeness testing, sometimes it is to our advantage to simply estimate each probability value, rather than use the more sophisticated algorithm of [4]. This seemingly naive approach has another advantage: it gives an actual numeric estimate of the distances, instead of just an accept/reject answer. Here, we use this approach to obtain an additive approximation of the EMD of two unknown distributions over \( M \subset [0, \Delta]^d \) as follows.

**EMD-Approx** \( (p, q, \varepsilon) \)

1. Let \( G \) be the grid on \([0, \Delta]^d\) with side length \( \frac{\varepsilon}{4d} \), and let \( P \) and \( Q \) be the distributions induced by \( p \) and \( q \) on \( G \), with weights in each cell concentrated at the center.
2. Take \( O((4d \Delta / \varepsilon)^{d+2}) \) samples from \( P \) and \( Q \), and let \( \tilde{P} \) and \( \tilde{Q} \) be the resulting empirical distributions.
3. Return \( \text{EMD}(\tilde{P}, \tilde{Q}) \).

**Theorem 14** EMD-Approx takes \( O((4d \Delta / \varepsilon)^{d+2}) \) samples from \( p \) and \( q \) and, with probability \( 2/3 \), outputs an \( \varepsilon \)-additive approximation of \( \text{EMD}(p, q) \).

**Proof** Note that a sample from \( p \) or \( q \) gives us a sample from \( P \) or \( Q \), respectively, so it remains to prove correctness. Observe that \( |G| = (4d \Delta / \varepsilon)^d \), so \( G \) has \( 2^{(4d \Delta / \varepsilon)^d} \) subsets. By the Chernoff bound, with the \( O((4d \Delta / \varepsilon)^{d+2}) \) samples from \( p \), we can guarantee for each \( S \subset G \) that \( |P(S) - \tilde{P}(S)| > \frac{\varepsilon}{4d \Delta} \) with probability at most \( 2^{-(4d \Delta / \varepsilon)^d} / 3 \). By the union bound, with probability at least \( 2/3 \), all subsets of \( G \) will be approximated to within an additive \( \frac{\varepsilon}{4d \Delta} \). In that case,

\[
\| P - \tilde{P} \|_1 = \sum_{c \in G} |P(c) - \tilde{P}(c)| = 2 \max_{S \subseteq G} |P(S) - \tilde{P}(S)| \leq \frac{\varepsilon}{2d \Delta}.
\]
We then have, by Corollary $5 \ EMD(P, \hat{P}) \leq \varepsilon/4$. Further, since each cell has radius $\varepsilon/4$, we have $EMD(p, P) \leq \varepsilon/4$, giving us by the triangle inequality, $EMD(p, \hat{P}) \leq \varepsilon/2$. Similarly, $EMD(q, \hat{Q}) \leq \varepsilon/2$, so again by triangle inequality, we get

$$|EMD(p, q) - EMD(\hat{P}, \hat{Q})| \leq EMD(p, \hat{P}) + EMD(q, \hat{Q}) = \varepsilon,$$

completing our proof. □

5 Lower bounds

We can show that our tester is optimal for the 1-dimensional domain by a simple argument:

Theorem 15 Let $A$ be an $EMD$-closeness tester of distributions over any domain $M \subset [0, \Delta]$. Then $A$ requires $\Omega((\Delta/\varepsilon)^2)$ samples.

Proof Consider two distributions $p$ and $q$ over the domain $\{0, \Delta\}$, where $p$ is the distribution that puts the weight of $1/2$ at 0 and $\Delta$ and $q$ is the distribution that puts the weight of $1/2 + \varepsilon/\Delta$ at 0 and the weight of $1/2 - \varepsilon/\Delta$ at $\Delta$. Clearly $EMD(p, q) = \varepsilon$, and it is a classic result that distinguishing $p$ from $q$ requires $\Omega((\Delta/\varepsilon)^2)$ samples. □

Clearly this also implies the same lower bound for 2-dimensional domains, making our algorithm optimal in those cases. Next we prove that our $d$-dimensional tester is also essentially optimal in its dependence on $\Delta/\varepsilon$.

Theorem 16 There is no $EMD$-closeness tester that works on any $M \subset [0, \Delta]^d$ that takes $o((\Delta/\varepsilon)^{2d/3})$ samples.

Proof Suppose $A$ is an $EMD$-closeness tester that requires only $o((\Delta/\varepsilon)^{2d/3})$ samples. Then consider the following $\ell_1$-closeness tester for $\varepsilon = 1$:

$\ell_1$-Tester$(p, q, \varepsilon = 1)$

1. Let $G$ be a grid on $[0, \Delta]^d$ with side length $\Delta n^{-1/d}$
2. Let $f$ be an arbitrary injection from $[n]$ into the lattice points of $G$
3. Let $P$ and $Q$ be distributions on the lattice points of $G$ induced by $f$ on $p$ and $q$, resp.
4. return $A(P, Q, \frac{1}{2} \Delta n^{-1/d})$

Correctness is easy to see: if $p = q$, then clearly $P = Q$ as well and the tester accepts; alternatively, if $\|p - q\|_1 = 1$, then by Corollary $5$ and the observation that $\|P - Q\|_1 = \|p - q\|_1$,

$$EMD(P, Q) \geq \frac{\|P - Q\|_1}{2} \cdot \Delta n^{-1/d} = \frac{1}{2} \Delta n^{-1/d},$$

so the tester rejects, as required.
Now, to take a sample from $P$ (or $Q$), we simply take a sample $x$ from $p$ (or $q$) and return $f(x)$. Hence, the sample complexity of this tester is

$$o\left(\left(\frac{\Delta}{\frac{1}{2}\Delta n^{-1/d}}\right)^{2d/3}\right) = o(n^{2/3}).$$

But this contradicts the lower bound for $\ell_1$-closeness testing from \cite{Bhattacharyya2007, Karp2018}, completing our proof. 

If one of the distributions is known, we can similarly use the weaker $\Omega(n^{1/2})$ lower bound for uniformity testing to obtain the following theorem.

**Theorem 17** There is no EMD-closeness tester that works on any $M \subset [0, \Delta]^d$, where one of the input distributions is explicitly known, that takes $o((\Delta/\varepsilon)^{d/2})$ samples.

### 6 Clusterable distributions

Since the general technique of our algorithms is to forcibly divide the input distributions into several small “clusters,” it is natural to consider what improvements are possible when the distributions are naturally clusterable. We obtain the following substantial improvement from the exponential dependence on the dimension $d$ that we had in the general case.

**Theorem 18** If the combined support of distributions $p$ and $q$ can be partitioned into $k$ clusters of diameter $\varepsilon/2$, and we are given the $k$ centers, then there exists an EMD-closeness tester for $p$ and $q$ that requires only $\tilde{O}(k^{2/3}(d\Delta/\varepsilon)^4)$ samples.

**Proof** Let us denote the set of centers by $C = \{C_1, \ldots, C_k\}$. Consider the distributions $P$ and $Q$ on $C$ induced by $p$ and $q$, respectively, by assigning each point to its nearest center. If $EMD(p, q) > \varepsilon$, by Lemma 3 $\|p - q\|_1(d\Delta) > \varepsilon/2$. We can, of course, obtain samples from $P$ and $Q$ by sampling from $p$ and $q$, respectively, and returning the nearest center. Our problem thus reduces to $\ell_1$-testing for $(\frac{\Delta}{\varepsilon})$-closeness over $k$ points, which requires $\tilde{O}(k^{2/3}(d\Delta/\varepsilon)^4)$ samples using the $\ell_1$-tester from \cite{Bhattacharyya2007}. 

If we do not assume knowledge of the cluster centers, then we are still able to obtain the following only slightly weaker result.

**Theorem 19** If the combined support of $p$ and $q$ can be partitioned into $k$ clusters of diameter $\varepsilon/4$, then even without knowledge of the centers there exists an EMD-closeness tester for $p$ and $q$ that requires only $\tilde{O}(kd\Delta/\varepsilon + k^{2/3}(d\Delta/\varepsilon)^4) \leq \tilde{O}(k(d\Delta/\varepsilon)^4)$ samples.

To prove this, we need the following result by Alon et al. that was implicit in Algorithm 1 from \cite{Alon2007}.
Lemma 20 (Algorithm 1 from [1]) There exists an algorithm which, given distribution \( p \), returns \( k' \leq k \) representative points if \( p \) is \((k, b)\)-clusterable, or rejects with probability \( 2/3 \) if \( p \) is \( \gamma \)-far from \((k, 2b)\)-clusterable, and which requires only \( O(k \log k/\gamma) \) samples from \( p \). Moreover, if the \( k' \) points are returned, they are with probability \( 2/3 \) the centers of a \((k, 2b)\)-clustering of all but a \( \gamma \)-weight of \( p \).

Proof (of Theorem 19) By the lemma, if our distributions are \((k, \varepsilon/4)\)-clusterable, using \( \tilde{O}(kd\Delta/\varepsilon) \) samples we obtain a \((k', \varepsilon/2)\)-clustering of all but an \( \varepsilon/4d \)-fraction of the support of \( p \) and \( q \), with centers \( C' \). Note that the unclustered probability mass contributes at most \( \varepsilon/4 \) to the EMD. The theorem then follows from an identical argument as that of Theorem 18 (since we now know the centers).

Note that in general, if we assume \((k, b)\)-clusterability, this implies \( ((2b/\varepsilon)d^2, \varepsilon/2)\)-clusterability (by packing \( \ell_1 \) balls), where knowledge of the super-cluster centers also implies knowledge of the sub-cluster centers. Similarly, in the unknown centers case, \((k, b)\)-clusterability implies \( ((8b/\varepsilon)d^2k, \varepsilon/4)\)-clusterability. Unfortunately, in both cases we reintroduce exponential dependence on \( d \), so clusterability only really helps when the cluster diameters are as assumed above.

7 EMD over tree-metrics

So far we have considered only underlying \( \ell_1 \)-spaces (or, almost equivalently, \( \ell_p \)). We will now see what can be done for EMD over tree-metrics, and prove the following result.

Theorem 21 If \( p \) and \( q \) are distributions over the nodes of a tree \( T \), with edge weight function \( w(\cdot) \), then there exists an \( \varepsilon \)-additive-error estimator for \( \text{EMD}(p, q) \) that requires only \( \tilde{O}((Wn/\varepsilon)^2) \) samples, where \( W = \max_e w(e) \), \( n \) is the number of nodes of \( T \), and \( \text{EMD}(p, q) \) is defined with respect to the tree metric of \( T \). Moreover, up to polylog factors, this is optimal.

Proof First, let us consider an unweighted tree \( T \) over \( n \) points (i.e., where every edge has unit weight), with distributions \( p \) and \( q \) on the vertices. Observe that the minimum cost flow between \( p \) and \( q \) on \( T \) is simply the flow that sends through each edge \( e \) just enough to balance \( p \) and \( q \) on each subtree on either side of \( e \). In other words, if \( T_e \) is an arbitrary one of the two trees comprising \( T - e \),

\[
\text{EMD}(p, q) = \sum_e |p(T_e) - q(T_e)|.
\]

Then, with \( \tilde{O}(n^2/\varepsilon^2) \) samples we can, for every \( T_e \), estimate \( p(T_e) \) and \( q(T_e) \) to within \( \pm \frac{\varepsilon}{2(n-1)} \). This gives us an \( \varepsilon \)-additive estimator for \( \text{EMD}(p, q) \).

Generalizing to the case of a weighted tree, where edge \( e \) has weight \( w(e) \), we have

\[
\text{EMD}(p, q) = \sum_e w(e)|p(T_e) - q(T_e)|.
\]

It then suffices to estimate each \( p(T_e) \) and \( q(T_e) \) term to within \( \pm \frac{\varepsilon}{2w(e)(n-1)} \). Thus, \( \tilde{O}((Wn/\varepsilon)^2) \) samples suffice, where \( W = \max_e w(e) \).
Note that what we get is not only a closeness tester but also an additive-error estimator. In fact, even if we only want a tester, this is the best we can do: in the case where $T$ is a line graph (with diameter $n-1$), the standard biased-coin lower bound implies we need $\Omega(n^2/\varepsilon^2)$ samples.
