Abstract

As astronomers increasingly exploit the information available in the time domain, spectroscopic variability in particular opens broad new channels of investigation. Here we describe the selection algorithms for all targets intended for repeat spectroscopy in the Time Domain Spectroscopic Survey (TDSS), part of the extended Baryon Oscillation Spectroscopic Survey within the Sloan Digital Sky Survey (SDSS)-IV. Also discussed are the scientific rationale and technical constraints leading to these target selections. The TDSS includes a large “repeat quasar spectroscopy” (RQS) program delivering ∼13,000 repeat spectra of confirmed SDSS quasars, and several smaller “few-epoch spectroscopy” (FES) programs targeting specific classes of quasars as well as stars. The RQS program aims to provide a large and diverse quasar data set for studying variations in quasar spectra on timescales of years, a comparison sample for the FES quasar programs, and an opportunity for discovering rare, serendipitous events. The FES programs cover a wide variety of phenomena in both quasars and stars. Quasar FES programs target broad absorption line quasars, high signal-to-noise ratio normal broad line quasars, quasars with double-peaked or very asymmetric broad emission line profiles, binary supermassive black hole candidates, and the most photometrically variable quasars. Strongly variable stars are also targeted for repeat spectroscopy, encompassing many types of eclipsing binary systems, and classical pulsators like RR Lyrae. Other stellar FES programs allow spectroscopic variability studies of active ultracool dwarf stars, dwarf carbon stars, and white dwarf/M dwarf spectroscopic binaries. We present example TDSS spectra and describe anticipated sample sizes and results.

Key words: quasars: general – stars: variables: general – surveys

1. Introduction

With the massive photometric data sets expected from the next generation of time-domain imaging surveys, classification algorithms will become increasingly dependent on our understanding of cosmic variables. Recently, the Sloan Digital Sky Survey (SDSS)-IV (Blanton et al. 2017) extended Baryon Acoustic Oscillation Sky Survey (eBOSS; Dawson et al. 2016) has enabled spectroscopy of celestial variables through the Time Domain Spectroscopic Survey (TDSS). The TDSS has

Alfred P. Sloan Research Fellow.
been operational since 2014 August and had obtained 47,000 spectra of stars and quasars as of 2016 July. The target selection for the main TDSS single-epoch spectroscopy (SES) program, in which optical point sources (unconfirmed quasars and stars) are targeted based on variability for a first epoch of spectroscopy, prioritized to achieve a typical surface density on the sky of \( \sim 10 \deg^{-2} \), is described in Morganson et al. (2015). Initial results from a pilot SES survey during SDSS-III (Eisenstein et al. 2011) are presented in Ruan et al. (2016b).

Aside from the discovery and classification of the variable sky, the spectroscopic variability of some classes of objects is of considerable interest. For example, time-domain spectroscopy of broad absorption line (BAL) quasars was included in SDSS-III (e.g., Filiz Ak et al. 2012, 2013, 2014). Rather than be satisfied with extant SDSS spectroscopy for heterogeneously targeted objects, TDSS intentionally seeks repeat spectroscopic observations for subsets of known stars and quasars that are interesting astrophysically via several “few-epoch spectroscopy” (FES) subprograms. Keeping within the tight overall TDSS total fiber budget of \( \sim 10 \deg^{-2} \), each distinct FES subclass is approximately aimed to include of order \( 10^{3-5} \) objects per FES subclass, i.e., the minimum needed for a variety of reasons to achieve better than \( \sim 10\% \) statistics per subclass. With the actual FES subclasses implemented, this then means that of order \( \sim 10\% \) of the total TDSS fiber budget is allotted to FES, yielding an average target density of \( 1 \deg^{-2} \).

Recently, an eBOSS emission line galaxy (ELG) survey spanning 300 plates began observations in the fall of 2016 (Raichoor et al. 2017), covering some areas of the sky previously observed in SDSS-IV. For the TDSS fiber allotment of \( \sim 10 \deg^{-2} \) on these plates, we considered three main options for a targeting strategy: (i) probing deeper into the photometrically variable density, confirming new SES variables with enhanced completeness but reduced purity, (ii) re-observing previous SES targets, therefore obtaining repeat spectroscopy for variable quasars and stars in general, or (iii) shifting to a greater quasar emphasis, targeting more quasars previously observed in those fields. Since the ELG survey overlaps existing SDSS-IV fields as well as regions not yet covered by SDSS-IV, we adopted a new target selection for these plates, and chose to acquire repeat spectra of quasars already known in the field (option iii); this choice also serves as a pilot for a potentially larger program in future all-sky spectroscopic surveys. In this paper, we describe all the non-SES TDSS sub-programs that select objects for multiple spectroscopic observations, including several smaller SES programs covering the full SDSS sky area, and this pilot program of repeat quasar spectroscopy (RQS) on the \( \approx 1200 \deg^{3} \) area encompassed by the ELG plates.

Astrophysically, the main contributors to the variable sky, and thus the TDSS repeat spectroscopy sub-programs, are quasars and variable stars. The hallmarks of quasar spectra include the power-law continuum from a thermally emitting accretion disk, broad emission lines (BELs) from the broad line region (BLR) that are photoionized by a higher-energy UV continuum (Peterson 1993), and narrow emission lines (see the review by Osterbrock & Mathews 1986). The Balmer lines (H\( \alpha \), H\( \beta \), etc.) have historically been extremely useful for inferring information about the physical structure and dynamics of the BLR, and are directly related to the number of ionizing photons from the continuum source (Korista & Goad 2004). In rare cases, these lines can be double peaked when feeble winds allow a low optical depth sightline to the outermost part of the BLR disk (Eracleous et al. 2009). The Balmer lines also form the basis of our “Type I” versus “Type II” classification scheme, and repeat spectroscopy has been useful in the past to identify contaminants (e.g., with weak, broad Balmer emission lines) in samples of Type II quasars (Barth et al. 2014). The formation of other BELs is thought to involve more complicated processes (Waters et al. 2016). For example, the Mg I\( \beta \) BEL is subject to collisional de-excitation and can show different emission properties than the Balmer lines (Roig et al. 2014; Cackett et al. 2015; Sun et al. 2015). The UV lines (e.g., C IV, N V) are known to trace winds (Richards et al. 2011). BALs, found in 10%–25% of quasars (e.g., Weymann et al. 1991; Trump et al. 2006; Gibson et al. 2009), are believed to be formed in a wind that is launched from the accretion disk at 10–100 light days from the supermassive black hole (e.g., Murray et al. 1995; Proga 2000). A larger fraction of quasar spectra show narrow absorption lines (NALs; e.g., Lundgren et al. 2009), and some have absorption lines of intermediate widths (mini-BALs). The existence of BAL variability, which has been systematically studied since SDSS-III (Filiz Ak et al. 2012, 2013, 2014), has been known for almost three decades (see the review by Turnshek 1988).

The menagerie of stellar variable classes encompasses causes both intrinsic (e.g., pulsators like RR Lyrae, Cepheids, and long-period variables and eruptive stars like CVs, novae, and symbiotics) and observer-dependent (e.g., eclipsing and/or spectroscopic binaries and rotation) variables. Photometrically, a few percent of all stars are considered variable, with the exact number depending on the filter bands used, the cadence of observations, and the limiting magnitude of the sample. With dense photometric monitoring, a few percent of those will show periodic variability (arising from radial pulsations, rotation or orbital motion). The remaining variable stars exhibit eruptive or irregular variability, the latter class including flaring stars across the main sequence (e.g., Davenport 2016). The periodic stellar variables can be classified with reasonable efficiency based on their period, amplitude, and lightcurve shape (e.g., Palaversa et al. 2013; Drake et al. 2014; VanderPlas & Ivezić 2015). Spectroscopy provides further important physical characteristics such as gravity, temperature, and radial velocity. However, SES captures but a single phase, and may provide little insight into the physical reason for the observed variability. Multi-epoch spectra, in contrast, can provide key information about, e.g., radial velocity variations and orbital properties of binaries, or emission line variability related to chromospheric activity, irradiation, or accretion. Spectroscopic variability surveys in broad stellar samples are virtually nonexistent to date, but can broadly characterize stellar variability in physical detail, and also focus on specific classes of stars that are known or suspected to be variable.

We describe the TDSS input data sets used for choosing our spectroscopic targets in Section 2. In the following sections, we present the selection algorithms used by various subprograms of the TDSS to target objects for repeat spectroscopy, with the FES programs described in Section 3 and the RQS program in Section 4. We summarize these programs in Section 5.

---

28 Operationally, BALs have widths \( >2000 \, \text{km} \, \text{s}^{-1} \), NALs have widths \( <500 \, \text{km} \, \text{s}^{-1} \), and mini-BALs are in-between.
2. Input Data Sets

Spectra from the first two phases of the SDSS (York et al. 2000, also referred to as SDSS-I/II) form the basis of most samples targeted here. The SDSS legacy survey includes observations up through Data Release 7 (DR7) (Abazajian et al. 2009). The SDSS-III survey continued to extend the imaging and spectroscopic sky coverage of the SDSS surveys, culminating with DR12 (Alam et al. 2015). The SDSS-IV project eBOSS began in 2014 July, marking the formal start of TDSS observations. The most recent data release is DR13 (SDSS Collaboration et al. 2016).

We use imaging data from the SDSS-I/II/III and Pan-STARRS-1 (PS1; Kaiser et al. 2002) 3π surveys. The SDSS started its imaging campaign in 2000 and concluded in 2007, having covered 11,663 deg². SDSS-III added ~3000 deg² of new imaging area in 2008. PS1 imaging commenced in 2009 and provided light curves for all SDSS sources through 2013. Hence, the addition of the PS1 photometry to the SDSS photometry increases the span of light curves from ~8 to ~14 years. More details on each survey and the photometric variability measures used in (Section 3.4) and (Section 4) are described in this section.

2.1. SDSS Imaging

The SDSS uses the imaging data gathered by a dedicated 2.5 m wide-field telescope (Gunn et al. 2006), which collected light from a camera with 30 2k × 2k CCDs (Gunn et al. 1998) over five broad bands—ugriz (Fukugita et al. 1996; Doi et al. 2010)—in order to image 14,555 unique deg² of the sky. This area includes 7500 deg² in the North Galactic Cap (NGC) and 3100 deg² in the South Galactic Cap (SGC). The Eighth Data Release (DR8; Aihara et al. 2011) provides the full imaging data set and updated photometric calibrations. This catalog provides the magnitudes and astrometry used in constructing our target samples; all coordinates hereafter are J2000.

The Stripe 82 region of the SDSS (S82; −60° < α < 50° and |δ| < 1°27) covers ~300 deg² and has been observed ~60 times on average to search for transient and variable objects (Frieman et al. 2008; Abazajian et al. 2009). These multi-epoch data probe timescales ranging from 3 hr to 8 yr and provide well-sampled five-band light curves. The S82 variable and standard star catalogs (Ivezić et al. 2007) are used to train the TDSS SES selection in Morganson et al. (2015), and therefore the hypervariables selection (Section 3.4). The S82 data are used for variability selection in the RQS program (Section 4).

2.2. Pan-STARRS1 3π Survey

PS1 utilizes a 1.8 m telescope equipped with a 1.4-gigapixel camera. Over the course of 3.5 years of the 3π survey, up to four exposures per year in five bands, g, r, i, z, y, were taken across the entire δ > −30° sky (for full details, see Tonry et al. 2012; Metcalfe et al. 2013). Each nightly observation consists of a pair of exposures separated by 15 min to search for moving objects. For each exposure, the PS1 3π survey has a typical 5σ depth of 22.0 in the g-band (Inserra et al. 2013). The instrumentation, photometric system, and the PS1 surveys are described in Kaiser et al. (2010), Stubbs et al. (2010), and Magnier et al. (2013), respectively. A high-quality subset of PS1 data was first released in Processing Version 1 (PV1), and PV2 added data through a later date in the observing, as well as some previously missed earlier observations via better analysis failure handling (for an overall description of the PS1 database, see Flewelling et al. 2016).

2.3. Variability Measures

Whereas variability selection formed the basis for the first epoch (SES) target selection described in Morganson et al. (2015), multi-epoch imaging data were also used to select known stars and quasars for the extremely variable (or “hypervariable”; Section 3.4) and RQS quasar (Section 4) samples. The SES selection uses a three-dimensional parameter space (magnitude, PS1-only variability, and SDSS–PS1 difference), designed to achieve a high-purity variable sample at a typical surface density on the sky of ~10 deg⁻². As part of the SES selection, hypervariables were selected based on a single variability metric V that parameterizes variability in a two-dimensional space of two variability terms S₁ and S₂:

\[
V = (\text{median}(\text{mag}_{\text{PS1}} - \text{mag}_{\text{SDSS}}))^2 + 4 \text{median}(\text{Van}_{\text{PS1}})^2 / 2 = (S_1^2 + 4S_2^2)^{1/2},
\]

(Equation (11) of Morganson et al. 2015). Qualitatively, S₁ is the PS1–SDSS difference and represents long-term (multi-year) variability, and S₂ is the PS1-only variability characterizing short-term (days to a few years) variability. This non-standard variability measure was intended to combine short-term and long-term variability measures into one quantity. The training sets used to derive this quantity, as well as the detailed statistics of this selection, can be found in Morganson et al. (2015). Hypervariables with \( V > 2 \) mag were prioritized during the SES selection, whereas for the FES targets, a lower \( V \) threshold was used (see Section 3.4). As for the SES selection, an updated version of the “ubercalibrated” PS1 data (Schlafly et al. 2012), which include PV1 data up through 2013 July, was used to select FES hypervariables. For detailed definitions, see Morganson et al. (2015).

The RQS program targets known SDSS quasars based on median SDSS magnitude and highly significant variability (see Section 4). Here, the variability selection is based on the reduced \( \chi^2 \) of the light curve:

\[
\chi^2_{\text{pdf}} = \frac{1}{n - 1} \sum_{i=1}^{n} \left( \frac{m_i - \mu}{\sigma_i} \right)^2,
\]

where \( n \) is the number of data points in a given filter, \( m_i, ..., m_n \) are the individual magnitudes, \( \sigma_i \) is the error associated with \( m_i \), and \( \mu \) is the mean magnitude. The reduced \( \chi^2_{\text{pdf}} \) in both g and r bands is used to define the variability-selected subsamples (see Section 4 for detailed criteria). The \( \chi^2_{\text{pdf}} \) cuts remove noisy, sparse light curves where the variability is at low signal-to-noise ratio (S/N; e.g., see Figure 1), rather than removing quasars that do not intrinsically vary, since essentially all quasars should be variable in the absence of poor photometry or systematics (Butler & Bloom 2011).

For the \( \chi^2_{\text{pdf}} \) calculation, all primary and secondary SDSS photometric observations are considered, along with PS1 PV2 data, matched to within 1° and without regard to morphology or data quality flags. The PS1 data include observations up through 2013 December, and the error inflations derived in
Morganson et al. (2015) are applied. Point-spread function (PSF) magnitudes are adopted, as we are interested in the nuclear variability (e.g., in the case of resolved active galactic nuclei (AGNs)). Before the $\chi^2_{\text{pdf}}$ calculation, the SDSS magnitudes are transformed to the PS1 system as described in Morganson et al. (2015). We also first remove deviant points, as defined by being $>0.5$ mag from either the SDSS or PS1 running average. For this outlier rejection, we consider SDSS and PS1 data separately due to the gap in time between the two data sets. The outlier rejection is only applied to SDSS light curves with $n \geq 10$ points (i.e., Stripe 82 data), and to PS1 data with $n \geq 5$ points. To compute the running averages, we use a window of five points for SDSS data and three points for PS1 data. The outlier rejection affects 5% (10%) of the PS1 (Stripe 82) light curves. Among these, 12.5% (7%) of the PS1 (Stripe 82) epochs on average are removed as a result.  

Figure 1 shows example light curves for four sources with S82 and PS1 photometry and with different values of $\chi^2_{\text{pdf}}$. 

While this criterion could lead to the rejection of some interesting variables, we are mainly interested in maximizing the sample efficiency by rejecting spurious data points that may otherwise lead to a misleading variability measure.
2.4. Spectroscopic Data

All samples are constructed based on known spectroscopic classifications in SDSS. The BOSS spectrographs and their SDSS predecessors are described in detail by Smeee et al. (2013). SDSS-III BOSS (Dawson et al. 2013) significantly expanded the coverage in the SGC (approximately $-2^\circ < \delta < 35^\circ$, $-30^\circ < \alpha < 30^\circ$, see Figure 2), and revisited the entire NGC area. Since the RQS targets were planned before the start of SDSS-IV, they were restricted to SDSS-IV observations. SDSS-IV eBOSS observations are planned to cover the entire SGC BOSS footprint and almost the entire NGC, targeting mostly quasars and galaxies (Blanton et al. 2017). Since the RQS targets were compiled in summer 2016, they also draw from newly confirmed quasars targeted as part of SDSS-IV (Myers et al. 2015; Palanque-Delabrouille et al. 2016). The ELG survey (Raichoor et al. 2017) footprint covers most of S82, in particular the “Thin82” and “Thick82” regions outlined in Figure 2, totalling 620 deg$^2$ in the SGC. This area is also covered by eBOSS plates designed for luminous red galaxies (LRGs; Prakash et al. 2016) and quasar targets (including some that were observed after the SDSS-IV observations shown in Figure 2). The ELG footprint also includes 600 deg$^2$ in the NGC.

The wavelength coverage of the SDSS (BOSS) spectrographs is 3800–9200 Å (3600–10400 Å), with a spectral resolution ranging from 1850 to 2200 (1560–2650). The SDSS and TDDS spectra presented in this work all have $\lambda_{\text{eff}} = 54000$ Å, i.e., the plate holes were drilled to maximize the S/N at $\lambda_{\text{eff}}$, and the BOSS spectra either have $\lambda_{\text{eff}} = 54000$ Å or $\lambda_{\text{eff}} = 40000$ Å (Dawson et al. 2013). To accurately compare spectra with differing $\lambda_{\text{eff}}$, one must correct the spectra using the prescriptions given in Margala et al. (2016), Guo & Gu (2016), and Harris et al. (2016). Note that the Margala et al. (2016) corrections are applied in the DR14 release of spectra from the BOSS spectrographs (Abolfathi et al. 2017).

2.4.1. Quasar Catalogs and Temporal Baselines

As described by Richards et al. (2002), the bulk of SDSS quasar target candidates in SDSS-I/II were selected for spectroscopic observations based on their optical colors and magnitudes in the SDSS imaging data or their detection in the FIRST radio survey (Becker et al. 1995). Low-redshift, $z \lesssim 3$, quasar targets were selected based on their location in $ugri$-color space and the quasar candidates passing the $ugri$-color selection were selected to a flux limit of $i = 19.1$. High-redshift ($z \gtrsim 3$) objects were selected in $griz$-color space and are targeted to $i = 20.2$. Furthermore, if an unresolved, $i \lesssim 19.1$ SDSS object was matched to within 2$''$ of a source in the FIRST catalog, it was included in the quasar selection. Additional quasars were also (inhomogeneously) discovered and cataloged in SDSS-I/II using X-ray, radio, and/or alternate odd-color information, and extending to fiber-magnitudes of about $m < 20.5$ (e.g., see Anderson et al. 2003).

Unless otherwise stated, we select quasars for repeat spectroscopy from one of the visually vetted quasar catalogs: the SDSS-I/II DR5/7 quasar catalogs (DR5Q, DR7Q; Schneider et al. 2007, 2010; Shen et al. 2011) or the DR12 quasar catalog (DR12Q, final quasar catalog of SDSS-III; Páris et al. 2017). The RQS target selection considers confirmed SDSS-IV quasars from post-DR13 data (Myers et al. 2015; Palanque-Delabrouille et al. 2016), specifically the SpAll database version v5_9_1, which covers a region in the SGC (see Figure 2 and Table 2 for the SDSS-IV coverage at the time of target selection). The following SDSS-IV spectra are excluded from consideration.

1. Those objects lacking primary (mode $= 1$) magnitudes in DR10 (these objects are faint and few in number);
2. Those with OBJTYPE = SKY;
3. Those objects with morphological TYPE $= 0$, according to DR10 photometry; and
4. Those at redshift $z \gtrsim 0.8$ with morphological TYPE $= 3$, since a resolved quasar should be at a lower redshift.

In order to determine the number of existing spectra in Section 4, we extract all spectroscopy within 2$''$ from the SDSS DR12 SpecObjAll database. For the new SDSS-IV objects, we use the NSPEC field from SpAll-v5_9_1.

Figures 3 and 4 show the anticipated distribution of time lags between spectra for SDSS quasars. Figure 4 also shows the existing distribution of time lags and displays these distributions as a function of absolute magnitude $M_i$, where the $M_i$ values are estimated from the apparent $i$ magnitudes and distance modulus (no K-correction is applied). Note that these figures do not include the well-sampled quasar cadence from the SDSS Reverberation Mapping Program (Shen et al. 2015).

3. Few-epoch Spectroscopy

In addition to its main program to obtain initial characterization spectra of $>10^5$ optical variables selected from PS1, the TDDS includes nine separate, smaller FES programs to study spectroscopic variability. The FES programs target objects with existing SDSS spectroscopy among classes of quasars and stars of particular astrophysical interest to build statistical samples for follow-up study. These include, in approximate order of decreasing sample size: BAL quasars, the most photometrically

31 Note that the FES program approach is conceptually somewhat different than, and complementary to, the RQS approach. The RQS intentionally—and with fewer a priori biases—samples spectral variability across a much broader range of quasar subclasses, whereas the FES subclasses are more specific-science focused (e.g., BALQSOs), and therefore efficiently address some more restricted questions. The FES subclasses are custom-tuned and relatively smaller than the RQS, but still large in sample size in an absolute sense with hundreds to thousands each, providing excellent statistics, albeit attuned to more highly and specifically selected subsamples.
variable (“hypervariable”) quasars, high-S/N normal broad-line quasars, quasars with double-peaked or very asymmetric BEL profiles, hypervariable stars (including the most highly variable classical pulsators), active ultracool (late-M and early-L) dwarf stars with Hα emission, dwarf carbon stars, white dwarf/M dwarf spectroscopic binaries with Hα emission, and binary supermassive black hole candidates from Mg II broad line velocity shift analysis.

The FES programs and respective scientific goals and target selections are described in the following sections, starting with stars (Sections 3.1–3.4) and ending with quasars (Sections 3.4–3.8). The target flags used are listed in each subsection heading.

3.1. Magnetic Activity on Late-M and Early-L Dwarfs (TDSS_FES_ACTSTAR)

Magnetic activity is ubiquitous in stars at the transition between the M and L spectral types (ML dwarfs). In optical spectra, this activity is best identified with the Hα emission line, which traces chromospheric heating on these low-mass objects (e.g., Gizis et al. 2002; West et al. 2011). Hα is the optimal diagnostic in part because it is found in a relatively red portion of the spectrum, so is easier to observe for these very cool, red objects. Serendipitous and dedicated observations of Hα emission on multiple timescales have indicated Hα emission varies (sometimes dramatically; Hall 2002) on multiple timescales (e.g., Berger et al. 2009; Schmidt et al. 2015). Chromospheric heating covers only a small portion of the surface (<1% Schmidt et al. 2015), and those regions rotate in and out of view on timescales of hours to days (due to relatively rapid rotation; Reiners & Basri 2008) leading to Hα variability. On timescales of weeks to months, we expect the chromospheric emission regions to change in size due to underlying shifts in the magnetic field (similar to shifts in sunspots). Hα may also show variability over year- to decade-long timescales based on long-timescale magnetic field changes that are similar to the 11 year solar cycle. Analyses of Hα variability on ML dwarfs have so far been limited to ∼20 objects serendipitously observed by multiple groups, but the data indicate that 30%–50% of ML dwarfs exhibit significant variability over timescales that span months to years (Schmidt et al. 2015).

By comparing original spectra of ML dwarfs from the SDSS legacy survey with an additional spectrum from TDSS, we have a unique opportunity to monitor changes in Hα emission lines over timescales of 6–14 years. These observations can either be taken as indicators of the level of overall variability, or could be combined with data over shorter timescales to detect decadal magnetic cycles. The SDSS data for ML dwarfs also allow three-dimensional Galactic kinematics that can be leveraged to examine age and activity correlations among the multiepoch observations.

To select the FES sample of ML dwarfs, we combined the West et al. (2011) M dwarf and Schmidt et al. (2010) L dwarf catalogs. We selected a subset of dwarfs from these catalogs with magnitudes between 17 < i < 21 and spectral types from M7 to L3. We also required an average S/N > 3 per 1.5 Å pixel in the continuum surrounding Hα (6530–6555 Å and 6575–6600 Å) so that the presence and strength of Hα emission can be reliably measured (e.g., West et al. 2008). The dwarfs in our initial sample are contained in the BOSS Ultracool Dwarfs catalog (S. J. Schmidt et al. 2017, in preparation), and we required that each of them have a photometric distance (based on SDSS photometry), proper motion (from SDSS-2MASS-WISE positions) and radial velocity (based on SDSS spectroscopy) from that catalog. We also restricted the sample to dwarfs within 300 pc of the Galactic plane.

The selection criteria resulted in a total of 3739 M7, 534 M8, 153 M9, and 23 L dwarfs. To reduce the sample to ∼1000 ML dwarfs, we binned the data by height above the Galactic plane and restricted each 25 pc wide bin to 60 dwarfs randomly drawn from each spectral type. The final target list included 1036 stars (583 M7, 283 M8, 147 M9, and 23 L dwarfs). Initial data from the ML dwarf FES sample included dwarfs that have no change in their activity level as well as those that have
and the more recent epoch (3+2) has strong variable H absorber TDSS spectra, and the observed frame is shown.

is not yet known whether this behavior re
variable M dwarf is shown in Figure 5.
strong variability. The spectrum of a strongly active and
variable M dwarf is shown in Figure 5.

3.2. White Dwarf-M Dwarf Binaries (TDSS_FES_WDDM)

Recent studies have demonstrated that close binaries consisting of white dwarf-M dwarf pairs (WD-dM binaries) have a significant effect on the magnetic activity of their main sequence components (e.g., Morgan et al. 2012). The binary separations where increased magnetic activity is observed extend to ~100 au. While many of the WD-dM are unresolved photometrically, the two components can be separated in low-resolution spectroscopy due to their vastly different spectral energy distributions. While there is evidence of increased magnetic activity in close pairs, there has been limited analysis of the variability of magnetic activity in binary systems. Variability studies can distinguish among possible causes of activity (e.g., irradiation, accretion, disk disruption, and spin-up). This program aims to re-observe ∼400 WD-dM binaries identified via their spectral energy distributions. By measuring the magnetic activity of the M dwarf via the Hα equivalent width (EW), the goals are to determine (i) the effect of binary separation on the variability of magnetic activity, (ii) the effect of rotation on stellar activity in close binaries, and (iii) the WD cooling age, spectral type, orbital parameters, metallicity, and Galactic height, and the corresponding effects on magnetic activity.

Starting with the WD-dM binary sample of Morgan et al. (2012), targets that met the following criteria were selected:

1. within the magnitude range 17 < i < 21,
2. clear Hα emission from visual inspection,32 and
3. accurate proper motion measurements from the SDSS-USNOB proper motions table (MATCH = 1; PMRA and PMDEC ≠ 0; and DIST22 >7, where DIST22 is the distance to the nearest neighbor with q < 22). This criterion is necessary for the fiber holes to be drilled in the correct locations.

The resulting sample contains 402 active WD-dM pairs that span several M dwarf spectral types. An example of a binary with variable Hα is shown in the bottom panel of Figure 5.

3.3. Variability in Dwarf Carbon Stars (TDSS_FES_DWARFC)

Carbon in stellar atmospheres—indeed, most of the carbon in the universe—is produced by the triple-α process of helium fusion (3 He → 12 C) in the interiors of red giant stars. Strong carbon molecular bands are historically expected to be seen only in asymptotic giant branch (AGB) stars that have experienced a third “dredge-up” (Iben & Renzini 1983). However, among stars showing such C2 and CN molecular bands (C stars), the main sequence dwarf carbon stars (dCs) are numerically dominant in the Galaxy (Green et al. 1992). The accepted explanation for dCs is that they must all be in post-mass transfer binaries, where the former AGB star has since become a WD, leaving a carbon-enhanced dC primary. Indeed, a handful of “smoking gun” systems reveal evidence for this evolutionary scenario, having composite spectra with a hot DA WD component (Heber et al. 1993; Liebert et al. 1994; Green 2013; Si et al. 2014). While the connection has rarely been made in the literature, dC stars, having been rejuvenated by mass accretion, would likely be seen as blue stragglers if they were within a coeval stellar cluster. They are also probably the dwarf progenitors of the typically more luminous carbon-enhanced metal-poor (sgCH, CH) and perhaps barium (Ba II) stars, which all show carbon and s-process enhancements (see the discussion and references in De Marco & Izzard 2017). The detection of WD companions, and the characterization of the orbital properties of dC stars, are therefore important for understanding the mass transfer processes that give rise to this fascinating family of stars.

However, to date, the only dC star with a measured binary orbit is the prototype dC G77-61 (Dahn et al. 1977; Dearborn

32 We found that simple EW and S/N criteria with fixed wavelength intervals led to unreliable results if there were significant shifts in line location due to orbital motion of the close binaries. Preliminary EW and S/N values were therefore checked visually.
et al. 1986), a single-line spectroscopic binary (245 day period and semi-amplitude 20 km s⁻¹), where the WD has cooled to \( T_{\text{eff}} < 6000 \) K. Since G77-61 represents the only known dC with a proven radial velocity (RV) orbit, the mass-transfer hypothesis for dCs remains to be confirmed, and can be investigated only through the properties of dCs to detect and characterize host binary systems. Models for dC formation in both the disk and halo (de Kool & Green 1995) predict a bimodal orbital period distribution, with a large peak at \( \sim 10 \) au, and a smaller peak at \( \sim 1 \) au (for separations \( \lesssim 1 \) au) corresponding to systems that underwent a common envelope phase, where the companion was subsumed in the expanding atmosphere of the AGB star when it filled its Roche lobe. These models reproduce the better-studied distributions of CH and BaII giants, whose progenitors are almost certainly the dCs. The relic distribution of dC binary orbits should reveal the relative importance and efficiency of these types of accretion, which can substantially modify the dC, leaving it hotter and bluer (and perhaps more rapidly rotating) than expected for its age.

Green (2013) identified 1220 faint (\( r \gtrsim 17–21 \)) C stars from SDSS spectra, \( \sim \)five times more than previously known, but also including a wider variety of dC properties than past techniques such as color or grism selection have netted. From those with significant proper motion measurements, they identified 730 definite dwarfs, including eight systems with clear DA WD companions. This data set represents the first significant sample of \textit{bona fide} dCs appropriate for a population study.

The statistical analysis of large samples of sparsely sampled RV curves can be used to constrain the underlying properties (binary fraction and separation distribution) of the corresponding binary population (e.g., Maoz et al. 2012). The TDSS dwarf carbon star FES program will provide a second epoch of SDSS spectroscopy to measure RV variability for a large sample of dC stars, to produce first constraints on their binarity and the distribution of their orbital properties. The main aims of this program are to (i) test the binary evolution hypothesis for dC stars, (ii) constrain the distribution of orbital separations, and (iii) trace the chemistry and evolution of the oldest AGB stars. The strategy used in the program will: (i) measure the RV shift \( \Delta V \) for dC stars between SDSS and TDSS (5–18 years), and (ii) constrain the \textit{separation} distributions and hence the mass transfer mode.

For the dC FES program, we selected all 730 SDSS C stars from Green (2013) that were listed as dwarfs with high probability based on either their measured proper motions, or because they were identified from their SDSS spectra as composite DA/dC spectroscopic binaries. We added another 99 dC stars found by Si et al. (2014), totalling 829 unique dC stars for repeat spectroscopy within the TDSS. An example of SDSS archival and TDSS spectra of a dC in our program is shown in Figure 6.

### 3.4. \textit{“Hypervariable” Stars and Quasars (TDSS\_FES\_HYPSTAR, TDSS\_FES\_HYPQSO)}

This program targets the most highly photometrically variable stars/classical pulsators (defined as hypervariable stars), as well as hypervariable quasars in the TDSS. The spectroscopic variability for these objects can potentially reveal large structural changes in astrophysical sources, and is useful for finding rare, transient phenomena such as \textquotedblleft changing-look quasars\textquotedblright\ (e.g., LaMassa et al. 2015; MacLeod et al. 2016; Ruan et al. 2016a; Runnoe et al. 2016). More importantly, this program is exploring unknown territory and therefore the scientific returns could be quite substantial.

During the variable target selection in the main TDSS SES program (Morganson et al. 2015), hypervariables are identified using a modified variability characterization that is designed to work in the extreme regions of variability space (see Section 2.3). The hypervariable targets for these FES programs all have previous spectra in the SDSS DR11 SpecObjAll table. Since the pipeline classifications were adopted here without further verification, a few targeted stars may actually be quasars, and vice versa.

For stars, defined as \( i < 20 \) point sources (uncorrected for Galactic extinction) with \texttt{CLASS = STAR}, the top 0.5% most significantly variable objects were selected, corresponding approximately to \( V > 0.3 \) mag (see Figure 7). These sources lie outside an approximately elliptical contour with SDSS-PS1 difference of 0.2 mag, a PS1-only variability of 0.15 mag, or some intermediate combination of the two (see Figure 5, Morganson et al. 2015). The SDSS images of these sources are visually examined to remove objects with close neighbors, nearby diffraction spikes or other imaging issues that could significantly affect photometry. The above criteria select 1150 stars (\( \sim 0.05 \text{deg}^{-2} \)), which have the target flag \texttt{TDSS\_FES\_HYPSTAR}. Inspection of these targets’ initial SDSS spectra suggest that this sample is rich in RR Lyrae variables and also includes M dwarfs, carbon stars and stars that are difficult to classify. For an example target, see Figure 8.

For quasars, defined as \( i < 20 \) point sources (uncorrected for Galactic extinction) with \texttt{CLASS = QSO}, the top 2% most...
significantly variable objects were selected, corresponding to approximately $V > 0.5$ mag (see Figure 7). These sources lie outside an approximately elliptical contour with SDSS-PS1 difference of 0.7 mag, a PS1-only variability of 0.25 mag, or some intermediate combination of the two. The SDSS images of these sources are also visually examined to remove objects with close neighbors, nearby diffraction spikes or other imaging issues that could significantly affect photometry. The above criteria select 1555 quasars ($\sim 0.05$ deg$^{-2}$), which have the target flag TDSS_FES_HYPQSO. Inspection of these targets’ initial SDSS spectra suggest that this sample is rich in BAL quasars and blazars, but otherwise contains a wide range of quasar types (we leave a detailed census to a later publication). For example spectra, see Figure 8.

3.5. BAL Variations in Quasars (TDSS_FES_VARBAL)

This FES program will build upon recent systematic, sample-based studies of BAL variability (e.g., Barlow 1993; Lundgren et al. 2007; Filiz Ak et al. 2012, 2013, 2014; Vivek et al. 2014, and references therein) by re-observing $\sim$3000 BAL quasars from the SDSS and BOSS. About 2/3 of the sample was selected from Gibson et al. (2009) and has already been mostly observed as part of a BOSS ancillary proposal (see Filiz Ak et al. 2013) and probes rest-frame timescales of $\approx$4–7 years. The TDSS is obtaining a third spectroscopic epoch for this subsample, typically spanning an additional 1–3 years in the rest frame beyond the most recent BOSS observations. The TDSS data yield improved measurements of the dependence of BAL EW variability upon rest-frame timescale, enabling a test of the extent to which long-term variability trends found in the SDSS-I/II versus BOSS data persist. A third epoch also allows for the possibility of detecting BAL acceleration or re-emergence/disappearance. The long timescales sampled by this project are highly beneficial since velocity shifts associated with BAL acceleration/deceleration accumulate over time; the first results on this project’s BAL acceleration are presented in Grier et al. (2016).
Constraints upon BAL disappearance and emergence provide key insights into the lifetime of BALs. Furthermore, BAL re-emergence events at the same velocity argue strongly against models where the variability is due to gas motions, instead favoring models where ionization changes play a key role. The first results on BAL re-emergence/disappearance are presented in McGraw et al. (2017). Finally, these observations further characterize the coordinated EW variations of BAL quasars and BAL or X-ray-weak quasars selected for their unusual properties where observations of future variability (or lack thereof) may help determine the processes responsible for their unusual spectra.

After this addition, the resulting number of BAL quasars is 2481 (2005 regular plus 476 supplemental).

33 Two quasars have different redshifts between the two catalogs: J100424.88 +122922.2 and J153029.05 +553247.9. These inconsistencies are explained on page 759, column 2 of Gibson et al. (2009).

34 No explicit magnitude or S/N cut was made, but a very low S/N spectrum would have had to be quite interesting to be included.

3.5.1. Main BAL Sample

The steps to select the majority of FES BAL quasars are as follows.

1. Match the DR5 BAL catalog (Gibson et al. 2009) to the DR5Q. This catalog provides full positional, photometric, and spectroscopic information for each BAL quasar. Positions agree to within 0′′1 as expected. For the TDSS targeting, we adopt the astrometry as measured in SDSS DR9 (Ahn et al. 2012) for these objects.

2. Choose BAL quasars with $i < 19.28$. These $i$ magnitudes in the DR5 quasar catalog are not corrected for Galactic extinction, which is generally mild.

3. From the BAL quasars chosen in step 2, we only accept those with $B_{i0} > 100$ km s$^{-1}$ in one of their BAL troughs. Here, $B_{i0}$ is the modified balnicity index defined in Gibson et al. (2009). This cut removes weak BALs that could have been mis-classified due to, e.g., underlying continuum uncertainties.

We also constrain redshifts as follows (see Section 4 of Gibson et al. 2009): (i) 1.96–5.55 for Si IV BALs; (ii) 1.68–4.93 for C IV BALs; (iii) 1.23–3.93 for Al iii BALs; and (iv) 0.48–2.28 for Mg ii BALs. If a BAL quasar with troughs from multiple ions satisfies any one of these required redshift ranges, then it is accepted.

4. For the objects with coverage in the rest-frame window 1650–1750 Å, we only consider those with $S/N \geq 6$, where $S/N \geq 700$ is the S/N measurement in this wavelength window from the DR5 BAL catalog. This cut ensures a high-quality first-epoch spectrum for comparison purposes. The resulting number of BAL quasars is 2005.

5. At this point, a manual identification of 476 supplemental BAL targets was performed (led by author P. B. Hall). These targets may violate one or more of the above selection criteria, but have been identified as worthy of additional study nonetheless. They include the following object classes:

   (i) BAL quasars originally detected in the Large Bright Quasar Survey (Hewett et al. 2001) or FIRST Bright Quasar Survey (White et al. 2000), or otherwise having discovery spectra predating the SDSS by up to 10 years or more;

   (ii) redshifted-trough BAL quasars (Hall et al. 2013; Zhang et al. 2017), a rare class for which competing possible explanations make different predictions about trough variability;

   (iii) overlapping-trough BAL quasars with nearly complete absorption below Mg ii at one epoch but which in several cases (Hall et al. 2011; Rafiee et al. 2016) have already shown extreme variability;

   (iv) BAL quasars observed more than once by the SDSS and/or BOSS, and thus already possessing more than one epoch for comparison to SDSS-IV, including objects with BAL troughs which emerged between the SDSS and BOSS;

   (v) BAL or X-ray-weak quasars selected for their unusual properties where observations of future variability (or lack thereof) may help determine the processes responsible for their unusual spectra.

Figure 9 shows two examples of a variable BAL quasar observed in the TDSS. The selection recipes used to obtain these targets are detailed below in a step-by-step manner.

**Figure 9.** Top: example spectra of BAL troughs from TDSS (target class TDSS_FES_VARBAL, Section 3.5). The C IV BAL troughs for quasars SDSS J111728.75+490216.4 (Grier et al. 2016) and SDSS J091944.53+560243.3 (McGraw et al. 2017) are displayed in the top and bottom panels respectively, where the velocity is relative to the rest frame wavelength of C IV. In the top panel, the spectroscopic MJDs are 57129 (SDSS) and 52438 (SDSS); in the bottom panel they are 57346 (TDSS), 56625 (BOSS), and 59108 (SDSS). The lower panel shows an example of a BAL re-emergence. Bottom: SDSS J163709.31+414030.8, a candidate SBHB at $z = 0.760$ from Wang et al. (2017) showing a Mg ii velocity shift similar to those in the target class TDSS_FES_MGII (Section 3.6).
3.5.2. DR12 Objects

To increase the sky coverage of BAL targets, we employed a similar target selection as before for the BALs in a preliminary version of DR12Q from 2014 March 22 (I. Pâris 2014, private communication). To select BAL targets from this database, we focus only on C IV BAL selection, since this is arguably the primary ion of interest (and the one for which we had the needed data for selection). We require:

1. magnitude $i < 19.8$;
2. $BI > 100$ km s$^{-1}$, where BI is the balnicity index defined by the parameter $BI_{CIV}$ in Pâris et al. (2017);
3. BAL visual inspection flag to be positive ($BAL_{-FLAG_{VI}} = 1$); this cut only dismisses a few objects satisfying the $BI_{CIV} > 100$ km s$^{-1}$ requirement and thus is a small effect);
4. a redshift range $z = 1.68–4.93$, which provides complete coverage of the C IV BAL region;
5. coordinates within $-50^\circ < \alpha < 50^\circ$ and $17^\circ5 < \delta < 60^\circ$ (see above).

Application of these criteria produces 294 targets.

Finally, a manual identification of 313 additional special BAL targets was performed (led by author P. B. Hall). These targets may violate one or more of the above selection criteria, but have been identified as critical for study nonetheless. These objects were selected in two different ways.

1. 307 quasars were selected from the preliminary DR12 quasar catalog. All targets have ($BI_{CIV} > 0$ km s$^{-1}$) or ($BAL_{-FLAG_{VI}} = 1$) and one or more of the following: (i) O VI coverage (and preferentially narrow troughs); (ii) a high-velocity C IV trough ($>30,000$ km s$^{-1}$); (iii) possible redshifted absorption; (iv) an existing SDSS spectrum as well as a BOSS spectrum; and (v) some other unusual property, thus classifying it as an “odd-BAL.”
2. Six known quasars were selected from the printed catalogs of Junkkarinen et al. (1991, 1992) or Sosnowski et al. (1997).

In total, therefore, there are 294 + 313 = 607 BAL quasars from this second pass of BAL targeting.

3.6. Candidate Supermassive Binary Black Holes Based on Shifted Mg II Lines (TDSS_FES_MGII)

Supermassive black hole binaries (SBHBs) are thought to be a common consequence of the merger of two massive galaxies. According to the evolutionary scenario described by Begelman et al. (1980), sometime after the merger of the parent galaxies, the two black holes form a bound binary whose separation decays first by dynamical friction, then by scattering of stars, and finally by the emission of gravitational radiation.\(^35\) The slowest stage in this evolutionary scheme is thought to correspond to an orbital separation of $0.01$ pc $\lesssim a \lesssim 1$ pc. Thus, observational efforts have focused on finding SBHBs at these orbital separations using RV variations of the BELs (by analogy with double-lined or single-lined spectroscopic binary stars; e.g., Gaskell 1983, 1996). So far, direct observational evidence for SBHBs with two active black holes via this method has been elusive (e.g., Eracleous et al. 1997; Liu et al. 2016). Recent surveys have concentrated on candidate SBHBs with one active black hole and have utilized the large samples of quasar spectra available in the SDSS archive (Tsamantza et al. 2011; Eracleous et al. 2012; Ju et al. 2013; Shen et al. 2013; Liu et al. 2014; Runnoe et al. 2017). The general strategy of these surveys is to select quasars whose broad Balmer or Mg II lines are offset from the frame defined by the narrow lines by $\sim 1000$ km s$^{-1}$ or more and/or search for systematic RV variations between the first-epoch spectra and spectra taken several years later.

This program is a continuation of the work of Ju et al. (2013) who studied the broad Mg II emission lines of $0.36 < z < 2$ quasars with multiple SDSS observations. The spectra from this program can be used to detect velocity shifts in SBHBs with separations of $\sim 0.1$ pc and orbital periods of $\sim 100$ years, assuming that the black holes have masses of order $10^9 M_\odot$.

From the sample of all quasars in DR7Q with multiple SDSS spectra of the Mg II line, Ju et al. (2013) identified seven robust SBHB candidates along with 57 more candidates that were less secure, for a total of 64 targets. The program is designed to obtain a third-epoch spectrum for all candidates, with highest priority given to the seven robust candidates, in order to search for monotonic velocity shifts relative to the first epoch. The first results from this program were reported in Wang et al. (2017), in which the authors rule out a binary model for the bulk of candidates by comparing the variations in the velocity shifts over 1–2 years and 10 years. They also find that $\lesssim 10$% of active SMBHs reside in binaries with $\sim 0.1$ pc separations observed in the TDSS. The example shown in the bottom panel of Figure 9 is a candidate from Wang et al. (2017) with a prominent line shift.

3.7. Variability of Disk-like Broad Balmer Lines (TDSS_FES_DE)

Broad Balmer lines with double peaks, twin shoulders, or flat tops can be found in about 15% of radio-loud AGNs at $z < 0.4$ (Eracleous & Halpern 1994, 2003) and in about 3% of AGNs at $z < 0.33$ in the SDSS (Strateva et al. 2003), depending on radio-loudness and possibly Eddington ratio. Although a number of ideas have been discussed in the literature for the origin of these line profiles, a physical model attributing the emission to the outer parts of the accretion disk is the most successful in explaining the Balmer line profiles and other properties of these objects (see the discussion in Eracleous & Halpern 1994, 2003; Eracleous et al. 2009, and references therein). Thus, we refer to these objects as disk-like emitters hereafter. Previous long-term monitoring of disk-like emitters has sampled about two dozen objects over 20 years (e.g., Sergeev et al. 2000, 2017; Storchi-Bergmann et al. 2003; Gezari et al. 2007; Flohic 2008; Lewis et al. 2010; Popović et al. 2011, 2014, and references therein) at $z < 0.4$, most of which are radio loud.

This FES program expands the scope of past monitoring efforts by re-observing for at least one more epoch a much larger number of disk-like emitters drawn from the SDSS. This selection method leads to a much wider variety of objects than those targeted by previous campaigns, namely more luminous objects, objects with higher Eddington ratios, and radio-quiet objects. This program also targets objects at $z \sim 0.6$, which are even more luminous than those at $z < 0.4$.

Included in the target list are 1251 objects from DR7Q distributed over $\sim 6300$ deg$^2$ (i.e., $0.2$ deg$^{-2}$). The targets comprise “classic” disk-like emitters (at $z < 0.33$ taken from...
Strateva et al. 2003) and higher-redshift analogs (z \sim 0.6; from Luo et al. 2013), as well as additional objects identified by Shen et al. (2011). A total of 220 objects are “classic” disk-like emitters (objects whose Balmer profiles can easily be modeled by a rotating accretion disk; e.g., Eracleous et al. 2009) while the remaining objects have very asymmetric Balmer profiles that can plausibly be attributed to a perturbed disk (for example one with a prominent spiral) or to an SBHB (see Section 3.6). The magnitudes of the targets are i < 18.9. The TDSS spectra will cover Hα and Hβ for the z < 0.4 objects, and Hβ and Mg II for the z \sim 0.6 objects. The time baseline will be \textgreater 10 years for most objects. The 1251 targets of this program include 28 objects identified as promising sub-pc binary SMBH candidates with observed Hβ line shifts between two epochs in SDSS-I/II from Shen et al. (2013).

By combining existing SDSS spectra and those collected during the TDSS, this program aims to address the following scientific goals. First, the observations will empirically characterize the variability of the BEL profiles, i.e., determine what property of the profiles is varying (e.g., width, asymmetry, shift, relative strengths and velocities of the peaks or shoulders), as well as the magnitude and timescale of the variations. Second, the data will be compared to a wide array of models of disk perturbations, including warps, self-gravitating clumps, and spiral or other waves. Third, this program aims to determine whether the variations represent systematic drifts of the line profiles and evaluate whether these changes are consistent with RV shifts due to orbital motion in an SBHB.

An example of disk-like emitter variability seen in one of the targets of this program is shown in the top panel of Figure 10.

3.8. Variability of Broad Balmer Lines of Quasars with High-S/N Spectra (TDSS_FES_NQHISN)

This program will yield second (or third) epoch spectra of bright, low-redshift (z < 0.8) SDSS quasars with existing high-S/N spectra (requiring that the median S/N per spectral pixel across the full SDSS spectral range is \textgreater 23). The combination of old and new spectra will be used to study the general broad-line variability of quasars, including line shape changes and line centroid shifts, on multi-year timescales. The scientific goals are similar to those of the previous program (see Section 3.7). In addition to furthering our understanding of the dynamics of the gas in the broad-line region, the data from this program will be important for two more applications: (i) a comparison of the variability properties of typical quasar BELs to the variability properties of disk-like emission lines (see Section 3.7), and (ii) selection of SBHB candidates via velocity shifts.

The focus of this program is quasars in DR7Q at z < 0.8. Thus, the spectra will include the Hβ line, as well as the narrow [O III] doublet that will provide a reliable redshift and a velocity reference (e.g., Hewett & Wild 2010). Included in this sample are 1486 quasars with a median S/N \textgreater 23 per pixel.

For an example of a quasar targeted in this program, see Figure 10. This program is also producing serendipitous discoveries, for example the changing-look quasar from Runnoe et al. (2016) was identified from NQHISN spectra.

4. Repeat Quasar Spectroscopy

Quasar variability on multi-year timescales is poorly characterized for large samples, and our efforts to date have produced unexpected and exciting results on the (dis)appearance of broad absorption and emission lines (e.g., Filiz Ak et al. 2012; Runnoe et al. 2016) as well as large variability of the continuum and broad-line profile shapes. Clearly, in addition to continuing the existing TDSS programs, a more systematic investigation of quasar spectroscopic variability is warranted. As part of the eBOSS ELG survey (Raichoor et al. 2017), the TDSS was allotted a nominal target density of 10 deg⁻². As for previous plates, we reserve 10% of TDSS fibers for the FES programs described in Section 3. For the remaining fibers, we target known quasars for an additional epoch of spectroscopy (therefore, no SES targets were included on the ELG plates). The target list includes a magnitude-limited
sample of quasars to \( i < 19.1 \), accounting for the majority of targets (\( \lesssim 7 \text{ deg}^{-2} \)), and a variability-selected subsample based on the light curve \( \chi^2 \), favoring quasars with highly significant photometric variability. We also adopt the RQS target selection described here for the eBOSS plates covering the LRG/quasar targets within Thin82 (chunk20).

The RQS program is distinct from the SES TDSS target selection because (i) it targets known quasars for repeat spectroscopy so that spectroscopic variability can be studied; (ii) instead of a pure variability selection, it includes a complete magnitude-limited sample, where the targets are already known to be quasars; (iii) it uses the full SDSS+PS1 photometric variability information to populate fibers in the S82 region; (iv) it includes quasars with extended morphologies. Quasars with extended morphology are typically lower-luminosity, lower-redshift sources compared to the overall SDSS quasar sample, extended morphology are typically lower-luminosity, lower-

Since the density of SDSS quasars varies greatly across the SDSS footprint, with S82 being the densest, we apply these different cuts depending on the sky region to achieve an approximately uniform final target density. The nonuniform coverage of SDSS-IV quasars also alters our selection method from field to field. After the \( i < 19.1 \) selection (target flag \texttt{TDSS\_RQS1}), we either use a variability or magnitude cut to fill the remaining target density depending on the sky region, where variability-selected targets have a “v” appended to the target flag (e.g., \texttt{TDSS\_RQS2v}). A variability cut is especially useful in regions of high density since a magnitude cut would severely bias the selection to the brightest sources. Furthermore, the variability information is the best in the densest region (S82). Based on the final target densities, the bulk of the variability selected targets are in S82.

The target priorities are enumerated below for each region of the RQS footprint, where (1) is the highest RQS priority (target flag \texttt{TDSS\_RQS1} by including objects marked \texttt{TDSS\_RQS2} or \texttt{TDSS\_RQS2v}, we achieve a rather uniform surface density near the TDSS allotment of about 10 deg\(^{-2}\), although we supplied targets at a higher density than the nominal 10 deg\(^{-2}\) at lower priority to fill in any potential gaps in the ELG target density. In what follows, we adopt the J2000 coordinates from the DR10 \texttt{PhotObj} table.

(1) SGC ELG plates: Thin82 (chunk 21: 317\(^{\circ} < \alpha < 360\(^{\circ}\), 
\(-2^{\circ} < \delta < 2^{\circ}\)) and Thick82 (chunk 22: 0 < \( \alpha < 45^{\circ}\), 
\(-5^{\circ} < \delta < 5^{\circ}\))

(a) Region 1 (least dense): off S82, and currently lacking SDSS-IV coverage (see Table 2) All verified spectroscopic quasars with
1. \( \text{ip}_{PSF} < 19.1 \) or \( > 1 \) existing spectra for \( \text{ip}_{PSF} < 20.5 \).
2. \( \text{ip}_{PSF} < 20.8 \), which achieves a surface density near 11 deg\(^{-2}\).
3. \( \text{ip}_{PSF} < 21 \), which achieves a surface density near 15 deg\(^{-2}\).

(b) Region 2: off S82 with SDSS-IV coverage: All verified spectroscopic quasars with
1. \( \text{ip}_{PSF} < 19.1 \) or \( > 1 \) existing spectra for \( \text{ip}_{PSF} < 20.5 \).
2. \( \chi^2_{pdf} > 27 \) for \( \text{ip}_{PSF} < 20.5 \) to achieve 11 deg\(^{-2}\).
3. \( \chi^2_{pdf} > 15 \) for \( \text{ip}_{PSF} < 20.5 \) to achieve 15 deg\(^{-2}\).

(c) Region 3 (most dense): \( |\delta| < 1^{\circ}.3 \), in S82: All verified spectroscopic quasars with
1. \( \text{ip}_{PSF} < 19.1 \).
2. \( \chi^2_{pdf} > 57 \) for \( \text{ip}_{PSF} < 20.5 \) to achieve 11 deg\(^{-2}\).
3. \( \chi^2_{pdf} > 33 \) for \( \text{ip}_{PSF} < 20.5 \) to achieve 15 deg\(^{-2}\).

(2) Thin82 (chunk 20: 315\(^{\circ} < \alpha < 360\(^{\circ}\), 
\(-2^{\circ} < \delta < 2^{\circ}75\)):
1. \( \text{ip}_{PSF} < 19.1 \).
2. \( \chi^2_{pdf} > 57 \), which achieves a surface density near 11 deg\(^{-2}\).

---

36 In the NGC region with \( 126^{\circ} < \alpha < 133^{\circ}\), the full list of DR7–12 quasars, regardless of the number of photometric detections, forms our parent sample.

37 The density of \( i < 20.5 \) quasars with \( N_{spec} > 1 \) is 12.75 deg\(^{-2}\) and 1 deg\(^{-2}\) on and off Stripe 82, respectively.
5. Summary

We have described each sample that is targeted for spectroscopic reobservations in the TDSS. These targets include the FES samples, containing stars and quasars of astrophysical interest, and the RQS sample, containing a comprehensive set of quasars. For the single-epoch “SES” TDSS target selection, which constitutes the main TDSS sample, see Morganson et al. (2015); for initial results see Ruan et al. (2016b). By design, the FES programs total to an average target density of 1 deg^{-2} throughout the TDSS survey area (10% of all TDSS targets), whereas the RQS targets are prioritized to achieve a density of ~10 deg^{-2} over a smaller area (~1200 deg^{2}). Observations of the SES and FES programs began in 2014 July, and observations of the RQS targets started fall 2016. TDSS observations are planned to continue until mid-2020, as part of SDSS-IV eBOSS (see Blanton et al. 2017). By the end of the survey, the TDSS will have obtained reasonable statistical samples for each FES subclass, containing at least 100–1000 sources each, in addition to the ~13,000 new quasar spectra obtained by the RQS program (see Table 1).

The FES programs span a large range of scientific goals, including:

1. tracking magnetic field changes over weeks to months to decade-long timescales in M and L dwarfs through observed Hα variability (Section 3.1);
2. investigating the effect of rotation and orbital parameters on stellar activity via the H\alpha EW in WD–dM binaries (Section 3.2);
3. testing the binary evolution hypothesis for dC stars through RV shifts (Section 3.3);
4. exploring the hypervariable star and quasar populations (Section 3.4);
5. constraining models for BAL variability in quasars through analysis of BAL EW and profile variations over rest-frame timescales of \( \approx 4–10 \) years, including BAL acceleration and re-emergence/disappearance events (Section 3.5);
6. searching for velocity shifts in SBHBs with separations of \( \sim 0.1 \) pc and orbital periods of \( \sim 100 \) years (Section 3.6);
7. empirically characterizing the variability of BEL profiles in disk-like emitting quasars, informing models of disk perturbations (Section 3.7);
8. studying the general broad-line variability of quasars on multi-year timescales (Section 3.8).

The RQS program, comprising the bulk of the TDSS selection in the ELG and Thin82 plates, is intended to provide spectroscopic variability measurements for an unbiased, high-quality quasar sample that covers a wide range of redshift and luminosity. This data set will form a complementary sample to the existing quasar sample with repeat spectroscopy from the SDSS and BOSS, which contains 70K quasars as of DR14 (Pâris et al. 2017), and will span a larger range of timescales. Along with sampling long timescales, an important aspect of the FES and RQS programs is that repeat spectra obtained through RV shifts (\( \approx \) rest-frame timescales of \( \sim 4 \) years) are also of astrophysical interest.

All the raw and reduced data will be released to the public as part of the main SDSS-IV data releases. The spectroscopic variability studies addressed in these programs will improve our understanding of the variable sky and facilitate our preparation for future sky surveys in the time domain, such as Pan-STARRS-2 (Burgett 2012), the Zwicky Transient Facility (Bellm 2014), and the Large Synoptic Survey Telescope (LSST Science Collaboration et al. 2009). Additionally, the samples presented here will help establish the targeting strategy for future large-scale spectroscopic variability studies currently planned for after SDSS-IV.

We thank an anonymous referee whose comments greatly improved the manuscript. We also thank Lile Wang for provided the data needed for the bottom panel of Figure 9. Support for this work was provided by the National Aeronautics and Space Administration through Chandra Award Number AR4-15016X issued by the Chandra X-ray Observatory Center, which is operated by the Smithsonian Astrophysical Observatory for and on behalf of the National Aeronautics Space Administration under contract NAS8-03060. This material is based upon work supported in part by the National Science Foundation under Grants AST-1715121 and AST-1715763. W.N.B., C.J.G., and S.M. acknowledge support from NSF grant AST-1516784. Y.S. acknowledges support from an Alfred P. Sloan Research Fellowship and NSF grant AST-1715579. Funding for the Sloan Digital Sky Survey IV has been provided by the Alfred P. Sloan Foundation, the U.S. Department of Energy Office of Science, and the Participating Institutions. SDSS acknowledges support and resources from the Center for High-Performance Computing at the University of Utah. The SDSS web site is http://www.sdss.org/.

SDSS is managed by the Astrophysical Research Consortium for the Participating Institutions of the SDSS Collaboration including the Brazilian Participation Group, the Carnegie Institution for Science, Carnegie Mellon University, the Chilean Participation Group, the French Participation Group, Harvard-Smithsonian Center for Astrophysics, Instituto de Astrofísica de Canarias, The Johns Hopkins University, Kavli Institute for the Physics and Mathematics of the Universe (IPMU)/University of Tokyo, Lawrence Berkeley National Laboratory, Leibniz Institut für Astrophysik Potsdam (AIP), Max-Planck-Institut für Astronomie (MPIA Heidelberg), Max-Planck-Institut für Astrophysik (MPA Garching), Max-Planck-Institut für Extraterrestrische Physik (MPE), National Astronomical Observatories of China, New Mexico State University, New York University, University of Notre Dame, Observatorio Nacional/MCTI, The Ohio State University, Pennsylvania State University, Shanghai Astronomical Observatory, United Kingdom Participation Group, Universidad Nacional Autonoma de México, University of Arizona, University of Colorado Boulder, University of Oxford, University of Portsmouth, University of Utah, University of Virginia, University of Washington, University of Wisconsin, Vanderbilt University, and Yale University.

The Pan-STARRS1 Surveys (PS1) and the PS1 public science archive have been made possible through contributions by the Institute for Astronomy, the University of Hawai‘i, the Pan-STARRS Project Office, the Max Planck Society and its participating institutes, the Max Planck Institute for Astronomy, Heidelberg, and the Max Planck Institute for Extraterrestrial Physics, Garching, The Johns Hopkins University, Durham University, the University of Edinburgh, the Queen’s University Belfast, the Harvard-Smithsonian Center for Astrophysics, the Las Cumbres Observatory Global Telescope Network Incorporated, the National Central University of Taiwan, the Space Telescope Science Institute, the
National Aeronautics and Space Administration under Grant No. NNX08AR22G issued through the Planetary Science Division of the NASA Science Mission Directorate, the National Science Foundation Grant No. AST-1238877, the University of Maryland, Eotvos Lorand University (ELTE), the Los Alamos National Laboratory, and the Gordon and Betty Moore Foundation. 

Facilities: SDSS, Pan-STARRS.

Appendix

SDSS-IV Coverage

Table 2 lists the regions of sky relevant to the ELG survey (Raichoor et al. 2017) that had SDSS-IV coverage at the time of RQS targeting. This information would be necessary for reproducing the RQS target selection.
