SOLVING FOR HIGH DIMENSIONAL COMMITTOR FUNCTIONS USING NEURAL NETWORK WITH ONLINE APPROXIMATION TO DERIVATIVES

HAOYA LI, YUEHAW KHOO, YINUO REN, AND LEXING YING

Abstract. This paper proposes a new method based on neural networks for computing the high-dimensional committor functions that satisfy Fokker-Planck equations. Instead of working with partial differential equations, the new method works with an integral formulation that involves the semigroup of the differential operator. The variational form of the new formulation is then solved by parameterizing the committor function as a neural network. As the main benefit of this new approach, stochastic gradient descent type algorithms can be applied in the training of the committor function without the need of computing any second order derivatives. Numerical results are provided to demonstrate the performance of the proposed method.

1. Introduction

Understanding rare transition events between two states is important for studying the behavior of stochastic systems in physics, chemistry, and biology. One important method to describe the transition events is the transition path theory [7, 16, 20], and the central object in the transition path theory is the committor function. Assume that the transition between two states is governed by the overdamped Langevin process

\[ dx_t = -\nabla V(x_t) \, dt + \sqrt{2\beta^{-1}} \, dw_t, \]

where \( x_t \in \Omega \subset \mathbb{R}^d \) is the state of the system, \( V : \mathbb{R}^d \to \mathbb{R} \) is a smooth potential function, \( \beta = 1/T \) is the inverse of the temperature \( T \), and \( w_t \) is the standard \( d \)-dimensional Brownian motion. For two given simply connected domains \( A \) and \( B \) in \( \Omega \) with smooth boundaries, the committor function \( q(x) \) is defined as

\[ q(x) = P(\tau_B < \tau_A \mid x_0 = x), \]

where \( \tau_A \) and \( \tau_B \) are the hitting times for the sets \( A \) and \( B \), respectively. Many statistical properties of the transition are encoded in the committor function.

The committor function satisfies the Fokker-Planck equation (also known as the steady-state backward Kolmogorov equation)

\[ (-1/\beta \Delta + \nabla V \cdot \nabla) q = 0 \text{ in } \Omega \setminus (A \cup B), \quad q(x)|_{\partial A} = 0, \quad q(x)|_{\partial B} = 1. \]

If the potential \( V \) is confining, i.e. \( V(x) \to \infty \) as \( |x| \to \infty \) and the partition function \( Z_\beta = \int_{\mathbb{R}^d} \exp(-\beta V(x)) \, dx < \infty \) for any \( \beta > 0 \), then

\[ \rho(x) = \frac{1}{Z_\beta} \exp(-\beta V(x)) \]

is the equilibrium distribution of the Langevin dynamics (1). Under this condition, the Langevin process (1) is ergodic [18], which enables the use of Monte Carlo methods to sample from the
equilibrium distribution. For the rest of the paper we will always assume that $V$ is confining and $\rho$ exists.

One major difficulty in solving (3) is the curse of dimensionality. Various methods have been proposed under the assumption that the transition from $A$ to $B$ is concentrated in a quasi-one dimensional tube or low dimensional manifold. For example, the finite temperature string method [6, 21] approximates isosurfaces of the committor function with hyperplanes normal to the most probable transition paths, and updates the transition paths together with the isocommittor-surface. Diffusion map [3] solves for most probable transition paths, and updates the transition paths together with the isocommittor-function [6, 21] approximates isosurfaces of the committor function with hyperplanes normal to the one dimensional tube or low dimensional manifold. For example, the finite temperature string $A$ is proposed under the assumption that the transition from $B$ exists.

Let $\tau \equiv \tau_{A \cup B} = \min(\tau_A, \tau_B)$ be the hitting time of $A \cup B$. For a fixed small time step $\delta > 0$, we define the operator $P$ as follows:

\begin{equation}
(Pf)(x) := \mathbb{E}^x(f(x_{\tau_{A\delta}})),
\end{equation}

where $\mathbb{E}^x$ is the expectation taken with respect to the law of the process (7).

**Proposition 1.** When $\nabla V$ is bounded and Lipschitz continuous on $\mathbb{R}^d$, the solution to the committor function (3) satisfies the following semigroup formulation

\begin{equation}
q(x) = (Pq)(x) \quad \text{in} \quad \Omega \setminus (A \cup B), \quad q|_{\partial A} = 0, \quad q|_{\partial B} = 1.
\end{equation}

The proof of Proposition 1 is provided in Appendix A. The main advantage of working with (9) over (3) is that it does not contain any differential operator.

2. Proposed method

2.1. A new variational formulation. Consider the Langevin process starting from a point $x \in \Omega$

\begin{equation}
\begin{aligned}
& dx_t = -\nabla V(x_t) \, dt + \sqrt{2\beta^{-1}} \, dw_t, \\
& x_0 = x.
\end{aligned}
\end{equation}

Let $\tau_A$ and $\tau_B$ be the stopping time of the process hitting $\partial A$ and $\partial B$, respectively. Similarly, define $\tau \equiv \tau_{A \cup B} = \min(\tau_A, \tau_B)$ be the hitting time of $A \cup B$. For a fixed small time step $\delta > 0$, we define the operator $P$ as follows:

\begin{equation}
(Pf)(x) := \mathbb{E}^x(f(x_{\tau_{A\delta}})),
\end{equation}

where $\mathbb{E}^x$ is the expectation taken with respect to the law of the process (7).
For notational convenience, we introduce a function $r : \partial A \cup \partial B \to \mathbb{R}$ with $r(x)|_{\partial A} = 0$ and $r(x)|_{\partial B} = 1$. With this definition, the boundary condition of (9) is simply $q = r$ on $\partial A \cup \partial B$. In order to introduce the variational formulation, $Pq$ can be split into two parts as follows:

$$
(Pq)(x) = \mathbb{E}^x (q(x_{t+\delta})) = \mathbb{E}^x (q(x_{t+\delta}) \mathbf{1}_{\{\delta < \tau\}}) + \mathbb{E}^x (q(x_{t+\delta}) \mathbf{1}_{\{\delta \geq \tau\}})
$$

where the last equality results from the fact that $L$ is a generator. (13) can be compactly rewritten as

$$
\mathbb{E}^x (q(x_{t+\delta}) \mathbf{1}_{\{\delta = \tau\}})
$$

where $\mathbf{1}_{\{\delta = \tau\}}$ stands for the interior contribution and the second part of (10) as

$$
\mathbb{E}^x (q(x_{t+\delta}) \mathbf{1}_{\{\delta \geq \tau\}}),
$$

where the second equality uses Proposition 2. Since this is true for any continuous $\eta$ supported on $\Omega \setminus (A \cup B)$, we obtain (14).

$$
\min_{q} \frac{1}{2} \int_{\Omega \setminus (A \cup B)} q(x) ((I - P^i)q(x)) \rho(x)dx - \int_{\Omega \setminus (A \cup B)} q(x)P^br(x) \rho(x)dx
$$

The two formulations (14) and (13) share the same solution as shown below. Let $q^*$ be the solution to the variational problem (14) and $q(x, \epsilon) = q^*(x) + \epsilon \eta(x)$, where $\eta$ is continuous with compact support. By taking derivative with respect to $\epsilon$ at $\epsilon = 0$ we obtain

$$
0 = \frac{\partial}{\partial \epsilon} \left( \frac{1}{2} \int_{\Omega \setminus (A \cup B)} q(x, \epsilon) ((I - P^i)q(x, \epsilon)) \rho(x)dx - \int_{\Omega \setminus (A \cup B)} q(x, \epsilon)P^br(x) \rho(x)dx \right) \bigg|_{\epsilon = 0}
$$

$$
= \int_{\Omega \setminus (A \cup B)} \eta(x) ((I - P^i)q^*(x)) \rho(x)dx - \int_{\Omega \setminus (A \cup B)} \eta(x)P^br(x) \rho(x)dx
$$

$$
= \int_{\Omega \setminus (A \cup B)} \eta(x) ((I - P^i)q^*(x) - P^br(x)) \rho(x)dx,
$$

where the second equality uses Proposition 2. Since this is true for any continuous $\eta$ with compact support and $\rho(x) > 0$, we conclude that $(I - P^i)q^*(x) - P^br(x) = 0$ on $\Omega \setminus (A \cup B)$.

Plugging in the definitions of $P^i$ and $P^b$ into (14) leads to

$$
\min_{q} \frac{1}{2} \int_{\Omega \setminus (A \cup B)} q(x) ((I - P^i)q(x)) \rho(x)dx - \int_{\Omega \setminus (A \cup B)} q(x)(x) \rho(x)dx
$$

It is clear from this formulation that there is no need for taking gradient of $q(x)$ with respect to $x$.

Although there is no need to enforce the boundary conditions $q|_{\partial A} = 0$ and $q|_{\partial B} = 1$ explicitly in (14), one can still include the penalty terms that can sometimes give a better performance:

$$
\min_{q} \frac{1}{2} \int_{\Omega \setminus (A \cup B)} q(x) ((I - P^i)q(x)) \rho(x)dx - \int_{\Omega \setminus (A \cup B)} q(x)(x) \rho(x)dx
$$

$$
+ \frac{c}{2} \int_{\partial A} q(x)^2 dm_A(x) + \frac{c}{2} \int_{\partial B} (q(x) - 1)^2 dm_B(x),
$$
where $m_A$ and $m_B$ are measures supported on $\partial A$ and $\partial B$, respectively, and $c > 0$ is a penalty constant.

2.2. Nonlinear parameterization. In order to deal with the high dimensionality of the committer function $q(x)$, we propose to approximate $q(x)$ with an NN $q_\theta(x)$, where $\theta$ stands for the NN parameters. In terms of $\theta$, the optimization problem takes the form

$$
\min_\theta \frac{1}{2} \int_{\Omega \setminus (A \cup B)} q_\theta(x) \left( (I - P^\delta)q_\theta(x) \right) \rho(x) dx - \int_{\Omega \setminus (A \cup B)} q_\theta(x) P^\delta r(x) \rho(x) dx \\
+ \frac{c}{2} \int q_\theta(x)^2 dm_A(x) + \frac{c}{2} \int (q_\theta(x) - 1)^2 dm_B(x).
$$

When applying an stochastic gradient descent (SGD) to optimize (18), one needs to compute the derivative for each of the terms.

**Derivative of the first two terms.** By the symmetric property stated in Proposition 2, the derivative of the first two terms of (18) is

$$
\int_{\Omega \setminus (A \cup B)} \nabla_\theta q_\theta(x) \left( (I - P^\delta)q_\theta(x) \right) \rho(x) dx - \int_{\Omega \setminus (A \cup B)} \nabla_\theta q_\theta(x) P^\delta r(x) \rho(x) dx \\
= \int_{\Omega \setminus (A \cup B)} \nabla_\theta q_\theta(x) \left( q_\theta(x) - \mathbb{E}^x \left( q_\theta(x_\delta) 1_{\{\delta < \tau\}} \right) - \mathbb{E}^x \left( g(x_\tau) 1_{\{\delta \geq \tau\}} \right) \right) \rho(x) dx.
$$

Notice that (19) is an integral with measure $\rho(x) dx$. Therefore, if $x \sim \rho$ and $x_\delta$ follows (7), (19) can be written as

$$
\mathbb{E}_{x \sim \rho} \nabla_\theta q_\theta(x) \left( q_\theta(x) - \mathbb{E}^x \left( q_\theta(x_\delta) 1_{\{\delta < \tau\}} \right) - \mathbb{E}^x \left( g(x_\tau) 1_{\{\delta \geq \tau\}} \right) \right).
$$

An unbiased estimator for (19) in an SGD method is therefore

$$
\nabla_\theta q_\theta(x) \left( q_\theta(x) - q_\theta(x_\delta) 1_{\{\delta < \tau\}} - r(x_\tau) 1_{\{\delta \geq \tau\}} \right) = \nabla_\theta q_\theta(x) \left( q_\theta(x) - q_\theta(x_\delta) 1_{\{\delta < \tau\}} - 1_{\{\delta \geq \tau = \tau_B\}} \right).
$$

The significance of (21) is that one only needs to take the gradient once with respect to the parameter $\theta$, whereas in [10] one needs to take the gradient of both $x$ and $\theta$.

Let us comment on the implementation details of (21). First, the sample $x$ is supposed to be sampled from $\rho$. As mentioned previously, if the potential function $V$ is confining, then the Langevin process (1) is ergodic. This implies that the distribution of the samples $x_t$ generated from the stochastic differential equation (SDE) (7) converges to $\rho$ in the limit of $t \to \infty$. Therefore, after an initial burn-in period, the samples from the SDE trajectory follow the distribution $\rho$. There has been a large literature on how to solve SDE (7) numerically. The simplest method is the Euler-Maruyama scheme (see for example [12]). Let $\Delta t > 0$ be the time step size and $w_{\Delta t} \sim \mathcal{N}(0, \Delta t I_d)$, and $I_d$ is the $d$-dimensional identity matrix. The Euler-Maruyama approximation $\tilde{x}_{n\Delta t}$ at time steps $n\Delta t$ are computed via

$$
\tilde{x}_{(n+1)\Delta t} = \tilde{x}_{n\Delta t} - \nabla V(\tilde{x}_{n\Delta t}) \Delta t + \sqrt{2\beta^{-1}} w_{\Delta t}.
$$

Assuming ergodicity, the distribution $x \sim \rho$ can be approximated by $\tilde{x}_{N\Delta t}$ for a sufficiently small $\Delta t$ and sufficiently large $N$ with an arbitrary $\tilde{x}_0$.

Second, given $x \sim \rho$, one needs to sample $x_\delta$. We approximate $x_\delta$ by Euler-Maruyama scheme as well

$$
x_\delta = x - \nabla V(x) \delta + \sqrt{2\beta^{-1}} w_\delta,
$$

where $w_\delta \sim \mathcal{N}(0, \delta I_d)$.

Finally, it is necessary to determine the indicators $1_{\{\delta < \tau\}}, 1_{\{\delta \geq \tau = \tau_A\}}$ and $1_{\{\delta \geq \tau = \tau_B\}}$ in order to compute (21). For this, the following approximations are used

$$
1_{\{\delta < \tau\}} = 1 \text{ if } x_\delta \in \Omega \setminus (A \cup B), \quad 1_{\{\delta \geq \tau = \tau_A\}} = 1 \text{ if } x_\delta \in A, \quad 1_{\{\delta \geq \tau = \tau_B\}} = 1 \text{ if } x_\delta \in B.
$$

Intuitively these approximations should work well when $\delta$ is sufficiently small, which is also supported by the numerical experiments.
SOLVING FOR THE COMMITTOR FUNCTION WITH NEURAL NETWORK 5

It is worth mentioning that various importance sampling methods (see for example [15,19]) can potentially be used to approximate the integral in (20) and the corresponding gradients calculated above.

**Derivative of the penalty terms.** For the third and fourth terms of (18), unbiased estimators of their gradients are

\[
(23) \quad c \nabla_{\theta} q_\theta(x_A) q_\theta(x_A), \quad c \nabla_{\theta} q_\theta(x_B)(q_\theta(x_B) - 1),
\]

respectively, where \(x_A \sim m_A\) and \(x_B \sim m_B\).

**Connection with reinforcement learning.** Solving committor function can be viewed as a special case of the policy evaluation problem in reinforcement learning (RL): \(\Omega/(A \cup B)\) is the state space; the transition kernel is given by the operator \(P^i\) defined in (11); the discount factor is equal to one; there is no immediate reward for each individual step but the final reward is \((P^b g)(x)\); \(q(x)\) is the value function of the problem; (13) is the Bellman equation; and (21) is the temporal difference (TD) update.

However, the key difference with the general policy evaluation problem is that, due to the detailed balancing of overdamped Langevin dynamics, there is a variational formulation (14) for (13), which is not available for general RL problems except the special case considered in [17]. Because of the variational formulation, (21) is guaranteed to converge at least to a local minimum, even in the neural network parameterization. On the other hand, such a stability result fails to exist for neural network approximations for general RL problems, as many techniques and tricks are required in order for the neural network parameters to converge.

2.3. **Neural network architecture.** The architecture of the neural network \(q_\theta(x)\) follows the one used in [10] and is specifically designed for this problem. Below we briefly summarize the main design considerations.

In the low temperature regime, i.e. when \(T \to 0\), there is typically a sharp interface between \(A\) and \(B\), as pointed out by [10]. In order to account for this sharp transition, the tangent function \(\tanh\) is used as the activation function at the last nonlinear layer, as shown in Fig. 1.

In the high temperature regime, i.e. when \(T \to \infty\), there is another type of singular behavior. As \(T \to \infty\), the equation (3) converges heuristically to a Laplace equation with a Dirichlet boundary condition. When the domains \(A\) and \(B\) are relatively small, the solution near the boundary \(\partial A\) and \(\partial B\) are dictated asymptotically by the fundamental solution

\[
(24) \quad \Phi(x) := \begin{cases} -\frac{1}{2\pi} \log |x| & (n = 2) \\ \frac{1}{2\pi^{n/2} |x|^{n-2}} & (n \geq 3) \end{cases},
\]

where \(n\) is the inherent dimension of the Laplace equation of \(T \to \infty\), as demonstrated in [10]. For example, in the rugged-Muller problem 4.2, the inherent dimension \(n = 2\), while in the Ginzburg-Landau problem 4.3 we have \(n = d = 49\).

In order to address these two types of singular behaviors, we introduce the following parameterization

\[
(25) \quad q_\theta(x) := n_{\theta_A}(x)S_A(x - y^A) + n_{\theta_B}(x)S_B(x - y^B) + n_{\theta_0}(x),
\]

where \(y^A\) and \(y^B\) are the centers of \(A\) and \(B\), \(S_A(x - y)\) and \(S_B(x - y)\) are set to be fundamental solutions (24), with \(n\) depending on the inherent dimension of the problem. Finally, \(n_{\theta_A}, n_{\theta_B}\) are fully connected neural networks with ReLU activation, and \(n_{\theta_0}\) is a fully connected neural network with tanh activation at the last nonlinear layer and ReLU activation at other nonlinear layers. This architecture is summarized in Fig. 1.

3. **Lazy training analysis of the optimization**

When the learning rate approaches zero, the dynamics of the SGD can be approximated by the corresponding gradient flow (see [13] for example):

\[
(26) \quad \theta'(t) = -\nabla_{\theta} R(q_\theta), \quad \theta(0) = \theta_0,
\]
where in our case the loss function $R(\cdot)$ takes the form

$$R(q) = \frac{1}{2} \langle (I - P^i)q - P^b r, q \rangle_{\rho} + c \langle q, q \rangle_{m_A} + c \langle q - 1, q - 1 \rangle_{m_B},$$

with $\langle u, v \rangle_{m_A} = \int uvdm_A$ and $\langle u, v \rangle_{m_B} = \int uvdm_B$. In this section, we consider instead the rescaled gradient flow

$$\theta'(t) = -\frac{1}{\alpha^2} \nabla_{\theta} R(\alpha q_{\theta}), \quad \theta(0) = \theta_0,$$

with $R(\alpha q) = \frac{1}{2} \langle (I - P^i)(\alpha q) - P^b r, \alpha q \rangle_{\rho} + \frac{c}{2} \langle \alpha q, \alpha q \rangle_{m_A} + \frac{c}{2} \langle \alpha q - 1, \alpha q - 1 \rangle_{m_B}$, and analyze the training dynamics of $q_\theta$ in the lazy training regime. The reason for considering this rescaled formula is that the scaling effect caused by $\alpha$ arises in several situations, for example, when the weights of the NN are large in magnitude at initialization and the learning rate is small (see for example, [1, 2]).

In [2], it has been shown that when the scaling factor $\alpha$ is sufficiently large, the gradient flow (28) converges at a geometric rate to a local minimum of $F_{\alpha}(\theta) \equiv R(\alpha q_{\theta})/\alpha^2$, under some conditions that are detailed below.

**Theorem 3** [2]. Assume that: (1) $\theta \mapsto q_{\theta} \in \mathcal{F}$, where $\mathcal{F}$ is a separable Hilbert space; (2) $q$ is differentiable with a locally Lipschitz differential $\nabla_{\theta} q_{\theta}$; (3) $q_{\theta_0} = 0$ and $\text{rank} \nabla_{\theta} q_{\theta}$ is a constant in a neighborhood of $\theta_0$; (4) $R$ is strongly convex and differentiable with a Lipschitz gradient. Then there exists $\alpha_0 > 0$, such that for any $\alpha > \alpha_0$, the gradient flow (28) converges at a geometric rate to a local minimum of $F_{\alpha}$. 

In our setting, $\mathcal{F}$ is the separable Hilbert space $L^2_\nu((\Omega \setminus (A \cup B)) \cup \partial A \cup \partial B)$, where $\nu = \rho + cm_A + cm_B$ and the rescaled gradient flow is given by

$$\theta'(t) = -\frac{1}{\alpha} \left[ \langle (I - P^i)\alpha q_{\theta(t)} - P^b r, \nabla_{\theta q_{\theta(t)}} \rangle_{\rho} - c \langle \alpha q_{\theta(t)}, \nabla_{\theta q_{\theta(t)}} \rangle_{m_A} - c \langle \alpha q_{\theta(t)} - 1, \nabla_{\theta q_{\theta(t)}} \rangle_{m_B} \right].$$

The following result states the strong convexity of $R$. 

**Figure 1.** An example of the neural network architecture for a committor function and the corresponding loss. In this example we have two log $|x - y|$ type singularities.
Proposition 4. Assume that the operator $P^i$ defined in (11) has a corresponding probability density function $p^i(x, y)$ such that

$$P^i f(x) = \int_{\Omega \setminus (A \cup B)} p^i(x, y)f(y)dy,$$

and

$$\iint_{\Omega \setminus (A \cup B) \times \Omega \setminus (A \cup B)} p^i(x, y)p^i(y, x)dxdy < \infty.$$  

Then the quadratic form $f \mapsto (f, (I - P^i)f)_\rho$ is strongly convex on $L^2_\rho(\Omega \setminus A \cup B)$.

Based on Proposition 4, the following theorem is a direct consequence of Theorem 3.

Theorem 5. Assume that (30) and (31) hold, and $q_0 = 0$, and that $\text{rank} \nabla_\theta q_0$ is a constant in a neighborhood of $\theta_0$, then there exists $\alpha_0 > 0$, such that for any $\alpha > \alpha_0$, the gradient flow (29) converges at a geometric rate to a local minimum of $F_{\alpha}(\theta) = R(\alpha q_0)/\alpha^2$. 

4. Numerical experiments

This section presents the numerical results of the proposed method on several examples. The neural network architecture follows Fig. 1 and the stochastic gradient is computed following the description in Section 2.2. The training is carried out with the Adam optimizer [11]. Whenever the true solution $q^*$ is available, the performance is evaluated by the relative error metric:

$$E = \frac{\|q_\theta - q^*\|_{L^2_\rho(\Omega \setminus A \cup B)}}{\|q^*\|_{L^2_\rho(\Omega \setminus A \cup B)}}$$

computed on a validation dataset generated according to the distribution $\rho$. In all the experiments, 2000 samples are used for the boundary measures $m_A$ and $m_B$.

4.1. The double potential well. In this experiment, consider the committor function in the following double potential well:

$$V(x) = (x_1^2 - 1)^2 + 0.3 \sum_{i=2}^{d} x_i^2,$$

with $d = 10$ and the regions $A$ and $B$ defined as

$$A = \{ x \in \mathbb{R}^d \mid x_1 \leq -1 \}, \quad B = \{ x \in \mathbb{R}^d \mid x_1 \geq 1 \}.$$

The true solution can be easily obtained by letting $q(x) = \tilde{q}(x_1)$, such that it satisfies the one-dimensional ordinary differential equation (ODE)

$$\frac{d^2\tilde{q}(x_1)}{dx_1^2} - 4\beta x_1(x_1^2 - 1)\frac{d\tilde{q}(x_1)}{dx_1} = 0, \quad \tilde{q}(0) = 0, \quad \tilde{q}(1) = 1.$$

By solving this ODE numerically, we obtain a highly accurate approximation of the exact solution $q^*$.

Since the solution of this problem does not exhibit any singular behavior at the boundaries $\partial A$ and $\partial B$, $S_A(\cdot) = S_B(\cdot) = 0$ and the training is only performed for the component $n_{\theta_0}(\cdot)$ in (25). The problem is solved for the temperatures $T = 0.5$ and $T = 0.2$. Table 1 summarizes the numerical results and the training parameters. Notice that when the temperature $T$ is lower, the distribution $\rho$ is sparser in $\Omega \setminus (A \cup B)$. Therefore, more samples are used for $T = 0.2$ than for $T = 0.5$ in order to achieve a comparable precision. For example, for $T = 0.5$, $1.5 \times 10^5$ samples are used for $\Omega \setminus (A \cup B)$ and the relative error is $E = 0.014$. On the other hand, for $T = 0.2$, $8.0 \times 10^5$ samples are used and the relative error of the neural network solution is $E = 0.011$.

The numerical solution for $T = 0.5$ is shown in Fig. 2. The committor function $q_\theta$ represented by a neural network and the committor function $q^*$ obtained via solving (35) are plotted along the $x_1$ dimension for a fixed $(x_2, ..., x_d)$. The plot demonstrates that the NN committor function gives a satisfactory approximation to the true solution.
4.2. The rugged-Muller potential. In this example, we consider the committor function corresponding to the following rugged-Muller potential:

\[
V(x) = \tilde{V}(x_1, x_2) + \frac{1}{2\gamma^2} \sum_{i=3}^{d} x_i^2,
\]

where

\[
\tilde{V}(x_1, x_2) = \sum_{i=1}^{4} D_i e^{a_i(x_1 - x_i)^2 + b_i(x_1 - x_i)(x_2 - y_i) + c_i(x_2 - y_i)^2} + \gamma \sin(2k\pi x_1) \sin(2k\pi x_2)
\]

is the 2-dimensional rugged-Muller potential with the parameters

\[
\begin{align*}
[a_1, a_2, a_3, a_4] &= [-1, -1, -6.5, 0.7], & [b_1, b_2, b_3, b_4] &= [0, 0, 11, 0.6], \\
[c_1, c_2, c_3, c_4] &= [-10, -10, -6.5, 0.7], & [D_1, D_2, D_3, D_4] &= [-200, -100, -170, 15], \\
[X_1, X_2, X_3, X_4] &= [1, 0, -0.5, -1], & [Y_1, Y_2, Y_3, Y_4] &= [0, 0.5, 1.5, 1], \\
[\gamma, k, \sigma, d] &= [9, 5, 0.05, 10].
\end{align*}
\]

The domain of interest \(\Omega\) of this example is \([-1.5, 1] \times [-0.5, 2] \times \mathbb{R}^{d-2}\) and the regions \(A\) and \(B\) are the following two cylinders:

\[
A = \left\{ x \in \mathbb{R}^d \mid \sqrt{(x_1 + 0.57)^2 + (x_2 - 1.43)^2} \leq 0.3 \right\},
\]

\[
B = \left\{ x \in \mathbb{R}^d \mid \sqrt{(x_1 - 0.56)^2 + (x_2 - 0.044)^2} \leq 0.3 \right\}.
\]

In order to compute the error, \(q^*\) is solved approximately within the \(x_1x_2\)-plane. More precisely, we first apply finite element method on uniform grid to (3) in 2 dimensions with the potential \(\tilde{V}\), the domain \(\bar{\Omega} = [-1.5, 1] \times [-0.5, 2]\), and the regions \(\bar{A}\) and \(\bar{B}\) being the projection of the \(A\) and \(B\) defined in (39) onto the \(x_1x_2\)-plane. Once the 2-dimensional committor function \(\bar{q}\) is available, the approximation is \(q^*(x) = \bar{q}(x_1, x_2)\). The code of the finite element method is provided by the authors of [14].

As mentioned in Section 2.3, the singularity functions \(S_A\) and \(S_B\) should be set as the fundamental solutions of (3) when taking \(T \to \infty\). In this case, the limiting committor function as \(T \to \infty\) has the form \(q(x) = \bar{q}(x_1, x_2)\) that satisfies a 2-dimensional Laplace equation, the
fundamental solution to which has the form
\[ \Phi(x_1, x_2) = -\frac{1}{4\pi} \log((x_1 - a)^2 + (x_2 - b)^2). \]
Therefore, we set \( S_A = \log((x_1 + 0.57)^2 + (x_2 - 1.43)^2) \) and \( S_B = \log((x_1 - 0.56)^2 + (x_2 - 0.044)^2) \).
Numerical experiments are carried out when \( T = 22 \) and \( T = 40 \). In both situations, \( 6.0 \times 10^5 \) samples are used in \( \Omega \setminus (A \cup B) \). The relative errors are \( E = 0.024 \) when \( T = 22 \), and \( E = 0.023 \) when \( T = 40 \). Table 2 summarizes the numerical error and the parameters used in the experiments. The numerical solution is plotted in Fig. 3, where the exact solutions \( q^* \) are shown on the left

| \((T, \sigma)\)  | \(E\)  | \(\delta\) | \(c\) | No. training samples | Batch size | No. testing samples |
|-----------------|--------|------------|------|----------------------|------------|---------------------|
| (22, 0.05)      | 0.024  | 0.001      | 500  | \(6.0 \times 10^5\)  | 5000       | \(1.0 \times 10^6\)  |
| (40, 0.05)      | 0.023  | 0.001      | 500  | \(6.0 \times 10^5\)  | 5000       | \(1.0 \times 10^6\)  |

Table 2. Results for the rugged-Muller potential problem.

and the committor functions \( q_\theta \) represented by neural network are plotted on the right. The plots show that the NN approximation shows good agreement with the true solution.

![Comparison plots](image)

**Figure 3.** Comparisons between the NN represented committor functions and the ground truths. (a): The ground truth committor function for \( T = 22 \). 4.3. The Ginzburg-Landau model. The Ginzburg-Landau theory is developed to give a mathematical description of superconductivity [8]. In this example, we discuss a simplified Ginzburg-Landau phase transition model. The Ginzburg-Landau energy in one dimension is defined as:

\[
\tilde{V}[u] = \int_0^1 \left( \frac{\lambda}{2} u_x^2 + \frac{1}{4\lambda} (1 - u^2)^2 \right) dx,
\]

where \(\lambda\) is a small positive parameter and \(u\) is a sufficiently smooth function on \([0, 1]\) with boundary conditions \(u(0) = u(1) = 0\).

The high-dimensionality nature of the committor functions is a direct result of the discretization of \(u\). With a numerical discretization, \(u(x)\) is uniformly discretized by \(U = (U_1, \ldots, U_d)\) defined on a uniform grid on \([0, 1]\) with the boundary conditions \(U_0 = U_{d+1} = 0\). Then the continuous Ginzburg-Landau energy is approximated by a discrete one:

\[
V(U) := \tilde{V}_h[U] = \sum_{i=1}^{d+1} \frac{\lambda}{2} \left( \frac{U_i - U_{i-1}}{h} \right)^2 + \frac{1}{4\lambda} (1 - U_i^2)^2,
\]

where the grid size \(h = 1/(d+1)\). In this experiment we use \(h = 1/50\) and the dimension \(d = 49\).

\(V(U)\) has two local minima \(u_{\pm}(\cdot)\) shown in Fig. 4. The regions A and B are taken as the spheres \(\{U : ||U - u_{\pm}|| \leq r\}\), where \(|| \cdot ||\) is the Euclidean norm, and the radius \(r\) is chosen to be 3.

Based on the discretization used, \(d = 49\). According to Section 2.3, the singularities \(S_A \) and \(S_B\) are set to \(S_A = |U - u_-|^2 - d\), \(S_B = |U - u_+|^2 - d\). The numerical results are reported for the temperatures \(T = 30\) and \(T = 20\). For both cases \(2.0 \times 10^5\) samples are used in \(\Omega \setminus (A \cup B)\). In Table 3 we summarize the parameters used in the experiments with \(T = 30\) and \(T = 20\).

| \(T\) | \(\delta\) | \(c\) | No. training samples | Batch size |
|------|--------|------|----------------------|------------|
| 20   | 0.002  | 200  | \(2.0 \times 10^5\)  | 5000       |
| 30   | 0.001  | 200  | \(2.0 \times 10^5\)  | 5000       |

\textbf{Table 3.} Parameters for the Ginzburg-Landau problem.

In this problem, it is intractable to obtain the exact \(q^*\) due to the high dimensionality and therefore we are not able to estimate the relative error \(E\) directly. Instead, we study the region near the \(\frac{1}{2}\)-isosurface of committor function \(q_0\), which is defined as \(\Gamma_{\frac{1}{2}, \epsilon} = \{U : |q_0(U) - \frac{1}{2}| < \epsilon\}\). If \(q_0\) is indeed a satisfactory approximation of \(q^*\), then for a trajectory given by (7) starting from an arbitrary point \(x_0 \in \Gamma_{\frac{1}{2}, \epsilon}\), the probability of entering \(B\) before \(A\) should be close to \(\frac{1}{2}\).
More precisely, we first identify $m$ states $\{\tilde{x}_j\}_{j=1}^m$ on $\Gamma_{\frac{1}{2},\epsilon}$. From each $\tilde{x}_j$, $N$ trajectories are generated according to (7). Let us denote the number of trajectories reaching $B$ before $A$ as $n$. If the NN committor function is accurate, then by the central limit theorem, when $N$ is large, the distribution of $n/N$ should be approximately $\mathcal{N}(\frac{1}{2}, (4N)^{-1})$, i.e. the normal distribution with mean $\frac{1}{2}$ and variance $(4N)^{-1}$. In the actual experiment with $\epsilon = 0.01$, $m = 120$, and $N = 100$, the resulting statistics contain $n_j/N$ for $j = 1, 2, \ldots, 120$.

![Figure 5](image1.png)

**Figure 5.** Numerical results of the Ginzburg-Landau model when $T = 20$. (a): Empirical probability density function (PDF) of $\{n_j/N\}_{j=1}^{120}$ compared with the PDF of $\mathcal{N}(\frac{1}{2}, 1/400)$. (b): Q–Q (quantile-quantile) plot of $\{n_j/N\}_{j=1}^{120}$ versus $\mathcal{N}(\frac{1}{2}, 1/400)$.

![Figure 6](image2.png)

**Figure 6.** Numerical results of the Ginzburg-Landau model when $T = 30$. (a): Empirical PDF of $\{n_j/N\}_{j=1}^{120}$ compared with the PDF of $\mathcal{N}(\frac{1}{2}, 1/400)$. (b): Q–Q (quantile-quantile) plot of $\{n_j/N\}_{j=1}^{120}$ versus $\mathcal{N}(\frac{1}{2}, 1/400)$.

The numerical results we get when $T = 20$ and $T = 30$ are illustrated in Fig. 5 and Fig. 6, respectively. The histogram of $\{n_j/N\}_{j=1}^{120}$ is compared with the normal distribution $\mathcal{N}(\frac{1}{2}, 1/400)$ on the left, and the Q–Q (quantile-quantile) plot of the distribution of $\{n_j/N\}_{j=1}^{120}$ versus $\mathcal{N}(\frac{1}{2}, 1/400)$ is shown on the right. These figures demonstrate that the distribution of $\{n_j/N\}_{j=1}^{120}$ is in good agreement with the normal distribution $\mathcal{N}(\frac{1}{2}, 1/400)$. 
5. Conclusion

In this paper, we improve the method in [10] that solves for the neural network parameterized committor function. In particular, we show that the committor function satisfies an integral equation defined by the semigroup of the Fokker-Planck operator. The integrals in the variational form of this new equation can be conveniently discretized via sampling, and the committor function can be solved for using a neural network parameterization and stochastic gradient descent. The dynamics of the training process is studied analytically in the lazy training regime.

This work suggests a few directions of future research. First on the numerical side, the SDE (7) is currently integrated with the Euler-Maruyama method. It will be useful to explore higher order integration schemes. Our approximation for the stopping time is also rather primitive and it will be beneficial to explore better decision rules. Second, the proposed method can be readily applied to other high-dimensional partial differential equations that enjoy probabilistic interpretations.

APPENDIX A. Proof of Proposition 1

Recall that the Markov semigroup is defined as follows.

Definition 6. The Markov semigroup \((P_t)_{t \geq 0}\) associated with a Markov process \((x_t)_{t \geq 0}\) is defined as
\[
P_t f(x) = \mathbb{E}^x(f(x_t)) = \mathbb{E}(f(x_t) \mid x_0 = x), \quad t \geq 0, \quad x \in \Omega,
\]
where \(f : \mathbb{R}^d \to \mathbb{R}\) is bounded continuous.

Recall that \(\tau = \tau_{A \cup B}\). While \(\tau \wedge \delta\) cannot be directly plugged into Definition 6 since it is a random variable instead of a constant, the operator \(P_{\tau \wedge \delta} = P\) can still be defined by (8), and by the strong Markov property of the Langevin process \((x_t)_{t \geq 0}\), \((x_{\tau \wedge \delta})_{\delta \geq 0}\) is also a Markov process, thus \((P_{\tau \wedge \delta})_{\delta \geq 0}\) is a Markov semigroup. Now we proceed to the proof with the help of Dynkin’s formula described in the following theorem:

Theorem 7 [5]. Consider an Itô diffusion \((x_t)_{t \geq 0}\) defined by the following \(d\)-dimensional stochastic differential equation (SDE)
\[
dx_t = b(x_t) dt + \sigma(x_t) d\mathbf{w}_t.
\]
Let \(A\) be the infinitesimal generator of \((x_t)_{t \geq 0}\), which is defined by
\[
Af(x) = \lim_{t \to 0^+} \frac{P_t f(x) - f(x)}{t},
\]
where \(f \in D(A) := \{ f \in C_0(\mathbb{R}^d) \text{ such that the limit (44) exists} \}\), then for a stopping time \(\tau\) such that \(\mathbb{E}^x\tau < \infty\),
\[
\mathbb{E}^x[f(x_\tau)] = f(x) + \mathbb{E}^x \left[ \int_0^\tau Af(x_s) \, ds \right],
\]
for any \(f \in C_0^2(\mathbb{R}^d)\). Moreover, when \(\tau\) is the first exit time for a bounded set, (45) holds for any \(f \in C^2(\mathbb{R}^d)\).

For any fixed \(\delta > 0\), \(\tau \wedge \delta\) is a stopping time, and is bounded. Although the committer function \(q\) may not be compactly supported, we can still use the formula (45) with the stopping time \(\tau \wedge \delta\) replaced by \(\tau \wedge \delta \wedge \tau_{B_\delta}\), where \(B_\delta\) is the ball with the radius being \(r\) and the center being the origin. When \(\delta\) is sufficiently small and \(r\) sufficiently large, the difference between \(P_{\tau \wedge \delta}\) and \(P_{\tau \wedge \delta \wedge \tau_{B_\delta}}\) is negligible in practice, as long as \(V\) is a confining potential. For this reason, we continue to use the notation \(P = P_{\tau \wedge \delta}\) in the problem formulation instead of the more cumbersome \(P_{\tau \wedge \delta \wedge \tau_{B_\delta}}\).

Therefore for the solution \(q\) of the equation \((3)\), we have
\[
Pq(x) = q(x) + \mathbb{E}^x \left[ \int_0^{\tau \wedge \delta} -Lq(x_s) \, ds \right] = q(x), \quad \forall x \in \Omega \setminus A \cup B,
\]
as long as we can prove \(A = -L\). In order to show this, we introduce a result in [9].

Theorem 8 [9]. Assume that \(x_i\) satisfies the SDE (43). When \(a(x) = \sigma(x)\sigma(x)^\top\) and \(b\) are bounded and Lipschitz continuous, then the generator \(A\) of the semigroup associated with (43) has the following form.
\[
A = \frac{1}{2} \sum_{i,j=1}^d a_{ij}(x) \frac{\partial^2}{\partial x_i \partial x_j} + b(x) \cdot \nabla.
\]

Now we are ready to justify (46). For the Langevin process \((1)\), the coefficients are \(a_{ij}(x,t) = 1_{i,j=1}/\beta\), and \(b = \nabla V\), so the conditions in Theorem 8 on \(a\) are naturally satisfied. Since \(\nabla V\) is bounded and Lipschitz on \(\mathbb{R}^d\), the conditions in Theorem 8 on \(b\) are satisfied as well. Thus by Theorem 8, the generator \(A\) of \((P_t)_{t \geq 0}\) is
\[
A = \frac{1}{2} \sum_{i,j=1}^d \frac{1}{\beta} 1_{i,j=1} \frac{\partial^2}{\partial x_i \partial x_j} + \nabla V(x) \cdot \nabla = -L.
\]
Plugging this into Dynkin’s formula (45) yields (9), which is what we want to prove.
Appendix B. Proof of Proposition 2

Consider the stationary Langevin process, i.e. \( \{x_t\}_{t \geq 0} \) such that \( x_0 \sim \rho \) and \( x_t \) satisfies (1). It is known that this process is reversible (see for example [18]). In other words, we have
\[
E_{x \sim \rho} u(x_\delta) v(x) = E_{x \sim \rho} u(x) v(x_\delta),
\]
for any \( u, v \in L^2_\rho(\Omega \setminus A \cup B) \). Now since the law of the trajectory \( \{x_{\tau \wedge \delta}\}_{t \leq \delta} \) is the same as \( \{x_t\}_{t \leq \delta} \) as long as \( \delta < \tau \), we have
\[
E_{x \sim \rho} u(x) v(x_\delta) 1_{\{\delta < \tau\}} = E_{x \sim \rho} u(x) v(x_\delta) 1_{\{\delta < \tau\}},
\]
which is exactly \( \langle u, P^i v \rangle_\rho = \langle P^i u, v \rangle_\rho \).

Appendix C. Proof of Proposition 4

(30) can be rewritten as
\[
P^i f(x) = \int_{\Omega \setminus A \cup B} \frac{p^i(x, y)}{\rho(y)} f(y) \rho(y) dy,
\]
and when (31) holds, we have
\[
\int_{\Omega \setminus A \cup B} \int_{\Omega \setminus A \cup B} \left( \frac{p^i(x, y)}{\rho(y)} \right)^2 \rho(x) \rho(y) dx dy = \int_{\Omega \setminus A \cup B} \frac{p^i(x, y)}{\rho(y)} \rho(x) p^i(x, y) dx dy = \int_{\Omega \setminus A \cup B} \frac{p^i(x, y)}{\rho(y)} p^i(x, y) dx dy < \infty,
\]
where in the second equality we used the symmetry of \( P^i \). Thus \( P^i \) is a Hilbert-Schmidt operator on \( L^2_\rho(\Omega \setminus A \cup B) \) [4]. Thus it is compact, and every point in its spectrum is an eigenvalue. Since \( P^i \) is contractive, all of its eigenvalues are less or equal than 1, and it suffices to prove that 1 is not an eigenvalue for \( P^i \). If 1 was an eigenvalue of \( P^i \), then there exists a nonzero function \( f \in L^2_\rho(\Omega \setminus A \cup B) \) such that \( P^i f = f \), and by using (30) \( n \) times, we get
\[
f(x) = \int_{\Omega \setminus A \cup B} p^i(x, y) f(y) dy = \int_{\Omega \setminus A \cup B} p^i(x, y) p^i(x, z) f(z) dy dz = \cdots = E^x (f(x_\delta) 1_{\{\delta < \tau\}}), \quad \forall n > 0.
\]
But the Langevin process (1) is ergodic, and the equilibrium measure \( \rho \) is positive, so \( 1_{\{\delta < \tau\}} \rightarrow 0 \) almost surely when \( n \rightarrow \infty \), resulting in \( f = 0 \), which contradicts with the assumption that \( f \) is nonzero. This contradiction shows that 1 is not an eigenvalue of \( P^i \) and closes the proof.
