Abstract.

It is known that galactic potentials can be kinematically linked to the observed red/blue shifts of the corresponding galactic rotation curves under a minimal set of assumptions (see [1] and [2] for details): \textit{i}) that emitted photons come to us from stable timelike circular geodesic orbits of stars in a static spherically symmetric gravitational field, and \textit{ii}) that these photons propagate to us along null geodesics. This relation can be established without appealing at all to a concrete theory of gravitational interaction. This kinematical spherically symmetric approach to the galactic rotation curves problem can be generalized to the stationary axisymmetric realm, which is precisely the symmetry that spiral galaxies possess [3]. Here we review the relativistic results obtained in the latter work. Namely, by making use of the most general stationary axisymmetric metric, we consider stable circular orbits of stars that emit signals which travel to a distant observer along null geodesics and express the galactic red/blue shifts in terms of three arbitrary metric functions, clarifying the contribution of the rotation as well as the dragging of the gravitational field. This stationary axisymmetric approach distinguishes between red and blue shifts emitted by circularly orbiting receding and approaching stars, respectively, even when they are considered with respect to the center of a spiral galaxy, indicating the need of precise measurements in order to confront predictions with observations. We also point out the difficulties one encounters in the attempt of determining the metric functions from observations and list some potential strategies to overcome them.

1. Introduction

The galactic rotation curves provide a direct method of determining the gravitational field inside a spiral galaxy since they have been measured for a great amount of galaxies [4]–[9]. These curves are obtained by measuring the red/blue shifts of light emitted from stars and from the 21 cm radiation from neutral gas clouds. The observations show evidence that the red/blue shifts $z$, or equivalently, the tangential velocities of rotation $v$, remain constant or decay more slowly than the Keplerian behaviour ($v^2 \sim 1/r$) up to distances far beyond the luminous radius of these galaxies. By performing a naive Newtonian analysis of this effect, one deduces that the energy density of the galaxies decreases approximately as $r^{-2}$, and hence, the mass of these bodies should increase as $m(r) \approx r$. Since the observed luminous galactic components do not produce this growing behaviour, a question arises: what is the reason of such an effect? Nowadays there
is a strong believe that dark matter is responsible for it, being the major bounded constituent of galaxies and galaxy clusters (∼25% of the total energy density of our Universe [10]). However, one can naturally ask whether this large unseen mass does not produce a relevant gravitational red shift. On the other hand, in [11] it was shown for a large and complete sample of spiral galaxies that their luminous regions consist of stellar discs embedded in universal dark halos of constant density independently of the galaxy properties; moreover, it was shown that the Dark Matter halos made by the most likely dark particle are inconsistent with actual observations. Finally, alternative approaches to this problem like modifications of Newtonian dynamics based on these observations have also been developed [12]–[16]. In this review we shall analyze the problem on the basis of what is directly observed: the photons red/blue shifts. This approach enables us to keep track of the effect of the underlying made assumptions, and to be aware of when they are not longer valid.

There have been previous relativistic approaches to the galactic rotation curves problem that make use of stationary axisymmetric metrics within the framework of general relativity. For instance, Matos et al. [17] have shown that the expression for the tangential velocity of test objects which follow a circular stable geodesic orbit in the equatorial plane can be expressed as a function of arbitrary metric coefficients of an axisymmetric static space-time. On the other hand, within the comoving dust solution of Cooperstock and collaborators (see e.g. [18]–[23]) it is claimed that the known data from galactic rotation curves can be described by non-linear general relativistic effects in galactic dynamics with at most relatively little extra matter. A crucial issue within this approach is that even though fields and velocities are small in a galaxy, it is not consistent to describe galactic dynamics through a Newtonian approximation since there are non-linear contributions of non-negligible size coming from Einstein equations. However, these models have received criticisms in several directions that point out to unphysical features like the need of an additional exotic matter source in the galactic disc [24] or infinite mass at large distances [25], the presence of singularities when continuing the interior solution into a consistent exterior configuration [26], the inconsistency of the use of comoving frames with the condition of differential rotation in a galaxy [27], etc. An important observation upon this model was pointed out in [28], namely, the stationary axisymmetric metric of the comoving dust solution of [18] does not possess the most general form since it has only three arbitrary functions instead of four, moreover, their assumed Weyl gauge (W = r) is not consistent with the Einstein equations since this metric function is not harmonic and hence, it does not belong to the most general class of stationary axisymmetric solutions, the Lewis-Papapetrou class, a circumstance that might be connected with the problems of the model.

The aim of this review paper is to provide a stationary axisymmetric kinematical description of the galactic rotation curves problem since this is a more realistic symmetry compared to the spherical one when studying spiral galaxies: the most accepted composition of spiral galaxies indicates that its main mass constituent is concentrated in a thin disc with a central bulge which are surrounded by a spherical halo [29]. Thus, it is commonly accepted that the main aspects of the galactic dynamics can be approximately described by (rotating) thin galactic disc models. We make use of the most general stationary axisymmetric metric and express the galactic red/blue shifts measured by a distant observer, that can in principle be compared to observations provided by astronomers, in terms of three arbitrary metric functions. We also clarify the contribution of the rotation and the dragging of inertial frames due to the gravitational field. We further point out the difficulties we have when determining the metric functions from observations without making reference to any theory of gravitational interactions, and comment on some possible ways to overcome them.
2. Stationary Axisymmetric Rotation curves

We shall start by assuming that stars behave like test particles which follow time-like geodesics of a rotating axially symmetric space-time associated with galactic discs which possess such a symmetry. The most general line element for a space-time of this kind has the following form:

$$ds^2 = -e^{2\Phi} dt^2 + Q^2 dr^2 + R^2 \left[ d\theta^2 + \sin^2 \theta \left( d\varphi - W dt \right)^2 \right],$$  

(1)

where $\Phi$, $Q$, $R$ and $W$ are all functions of $r$ and $\theta$. We shall also consider two observers $O_e$ and $O_d$ with 4-velocities $u^\mu_e$, $u^\mu_d$, respectively. Observer $O_e$ corresponds to the light emitter (i.e., to the stars placed at a point $P_e$ of space-time), and $O_d$ represents the detector at point $P_d$, which is located far away from the light emitter and is ideally located at $r \rightarrow \infty$.

We further assume that stars move on the galactic plane and, thus, the polar angle can be fixed $\theta = \pi/2$, so that $u^\theta_e = (0, 0, 0, 0)_e$, where $U^\mu_e = \dot{x}^\mu$ and the dot stands for derivation with respect to the proper time of the particle (of the star).

On the other hand, the 4-velocity of the detector located “far away” from the source, in a stationary axisymmetric background, is given by $u^\mu_d = (U^t, U^r, 0, 0)_d$, where $U^\mu_d = \dot{x}^\mu$ and the dot stands for derivation of the object (of the observer) due to the rotation of the galaxy. This effect must be taken into account when considering the measurement of red/blue shifts of light signals emitted in our own galaxy or in galaxies “close” to ours, for instance. However, if the studied red/blue shifts correspond to galaxies located “far away” from us, so that we can neglect the dragging effect, then we can consider that the detector is static, i.e., that the $O_d$‘s 4-velocity is tangent to the static Killing field $\partial_t$, and hence its 4-velocity is given by $u^\mu_d = (U^t, U^r, 0, 0)_d$. Later on we shall give a qualitative estimation of whether we can consider this ideal limit (when the dragging effect can be neglected) in terms of the contribution of the angular velocity of a given galaxy to the measured red/blue shift.

We further normalize the 4-velocity as usual ($u^\mu u_\mu = -1$), a condition which renders the following relation

$$-1 = g_{tt} (U^t)^2 + g_{rr} (U^r)^2 + g_{\varphi\varphi} (U^\varphi)^2 + 2 g_{t\varphi} U^t U^\varphi,$$  

(2)

The stationary axisymmetric metric (1) possesses two commuting Killing vectors: the time-like $\varepsilon^\mu = (1, 0, 0, 0)$ and the rotational one $\psi^\mu = (0, 0, 0, 1)$. The corresponding conserved quantities are the energy and the angular momentum per unit of mass at rest of the test particle and read

$$E = -g_{\mu\nu} \varepsilon^\mu u^\nu = - \left( g_{tt} U^t + g_{t\varphi} U^\varphi \right),$$  

(3)

$$L = g_{\mu\nu} \psi^\mu u^\nu = g_{r\varphi} U^r + g_{\varphi\varphi} U^\varphi.$$  

(4)

These relations are useful to obtain the expressions for $U^t$ and $U^\varphi$ in terms of the metric and these conserved quantities:

$$U^t = \frac{E g_{\varphi\varphi} + L g_{r\varphi}}{g_{t\varphi} - g_{tt} g_{\varphi\varphi}} = \frac{E - L W}{e^{2\Phi}},$$  

(5)

$$U^\varphi = -\frac{E g_{r\varphi} + L g_{tt}}{g_{t\varphi} - g_{tt} g_{\varphi\varphi}} = \frac{L}{R^2} + \frac{(E - L W) W}{e^{2\Phi}}.$$  

(6)

By introducing these 4-velocity components (5) and (6) in the line element (2) we get

$$g_{rr} (U^r)^2 = EU^t - LU^\varphi - 1,$$  

(7)

or, after multiplying by $e^{2\Phi}$ we equivalently have

$$e^{2\Phi} Q^2 (U^r)^2 + e^{2\Phi} + \frac{L^2 e^{2\Phi}}{R^2} - (E - L W)^2 = e^{2\Phi} Q^2 (U^r)^2 + V_{e\Phi}(E, L, g_{\mu\nu}) = 0.$$  

(8)
This equation resembles an energy conservation law for a non-relativistic particle with position dependent mass moving in an effective potential that depends on $E$ and $L$. This equation can be further reduced by considering that the orbits of stars are circular $U_r = 0$:

$$V_{\text{eff}} = e^{2\Phi} + \frac{L^2e^{2\Phi}}{R^2} - (E - LW)^2 = 0$$ (9)

Hence, once we have deleted the kinetic energy component in (8) one gets the expression for the effective potential on which the star moves (9). Thus, by deriving it with respect to the radial coordinate and setting the result to zero, we basically impose the minimum condition on the effective potential, a necessary condition to have circular orbits for the stars. This condition leads to the following expression for $E$:

$$E = LW - \frac{(e^{2\Phi} + \frac{L^2e^{2\Phi}}{R^2})'}{2LW'}$$ (10)

whereas from equation (9) we get the following relation:

$$E = LW + e^{\Phi}\sqrt{1 + \frac{L^2}{R^2}}$$ (11)

From both of these equations we see that the second term in the rhs of (10) must be positive definite, indicating that the numerator and the denominator must have opposite sign and leading to the following restriction:

$$\left(e^{2\Phi} + \frac{L^2e^{2\Phi}}{R^2}\right)' \gtrless 0 \quad \text{and} \quad W' \lesssim 0,$$ (12)

where the last two inequalities must be satisfied simultaneously in the sense that the numerator and the denominator of the aforementioned term must have opposite sign for positive $L$.

Moreover, from (10) and (11) we obtain the expression for the angular momentum $L$:

$$L_{\pm} = \frac{(W')^2 \pm |W'|\sqrt{(W')^2 + \frac{2R'(e^{2\Phi})'}{R^3} - \frac{(e^{2\Phi})'(\ln e^{\Phi})'}{R^2}}}{\frac{2}{R^2} \left\{\left[\left(\frac{e^{\Phi}}{R}\right)'\right]^2 - (W')^2\right\}},$$ (13)

where the following restrictions must be fulfilled in order to have a real angular momentum:

$$i) \quad (W')^2 \geq -\frac{2R'}{R^3} (e^{2\Phi})', \quad \text{equivalently,} \quad (W')^2 \geq (e^{2\Phi})' \left[(R)^{-2}\right]',$$ (14)

this condition makes real the square root of the second term in the radicand’s numerator; and

$$ii) \quad (W')^2 \pm |W'|\sqrt{(W')^2 + \frac{2R'(e^{2\Phi})'}{R^3} - \frac{(e^{2\Phi})'(\ln e^{\Phi})'}{R^2}} \gtrless 0,$$ (15)

or \quad $\left|\left(\frac{e^{\Phi}}{R}\right)\right|^' \gtrless |W'|$, (16)
where now the last two inequalities must have the same sign simultaneously, either positive or negative.

On the other side, for the energy $E$ we have from (11):

$$E_{\pm} = e^{\Phi} \sqrt{1 + \frac{(W')^2 \pm |W'|}{2 \left[ \left( \frac{e^{\Phi}}{R} \right)' \right]^2 - (W')^2}}$$

$$+ W \sqrt{1 + \frac{(W')^2 \pm |W'|}{2 \left[ \left( \frac{e^{\Phi}}{R} \right)' \right]^2 - (W')^2}}$$

(17)

Moreover, in order for the circular orbits of stars to be stable, we also need the second derivative of the effective potential to be positive:

$$\left[ e^{2\Phi} \left( 1 + \frac{L^2}{R^2} \right) \right]'' + 2L (E - LW) W'' - 2L^2 (W')^2 > 0,$$

(18)

where $L$ and $E$ must be replace by their expressions (13) and (17), respectively. It is worth noticing that relations (13) and (17), as well as the condition (18), can be reduced to the results obtained for the static spherically symmetric approach reported in [1] and [2] when $\theta = \pi/2$, $W = 0$ and $R = r$ under a simple coordinate transformation. For instance, by taking $N = e^{\Phi}$ we have:

$$E^2 = \frac{N^2}{1 - r \partial_r N/N}, \quad L^2 = \frac{r^3 \partial_r N/N}{1 - r \partial_r N/N}$$

(19)

and

$$E = \frac{e^{\Phi}}{\sqrt{1 - r \Phi'}}, \quad L = \frac{r \sqrt{r \Phi}}{\sqrt{1 - r \Phi'}},$$

(20)

which are precisely the expressions obtained by [1] and [2], respectively, for the energy and angular momentum.

It is well known that rotation curves of spiral galaxies are inferred from the red and blue shifts of the radiation emitted by stars that move in (nearly) circular orbits around the central region of the galaxy [4]–[7] and that light signals travel on null geodesics with tangent 4-momentum $k^\mu$. Here we shall make the assumption that $k^\mu$ are restricted to lie in the galactic plane $\theta = \pi/2$, and we shall evaluate the frequency shift of a light signal emitted from a star in a circular orbit represented by $O_e$ and detected by an observer represented by $O_d$. Moreover, we shall suppose that the galactic disc is edge-on directed towards the observer, a fact which implies that $k^\theta = 0.$

The frequency shift associated to the emission and detection of light signals is given by

$$1 + z = \frac{\omega_e}{\omega_d},$$

(21)

where the frequency of a photon measured by an observer with proper velocity $u^\mu|_{PC}$ reads

$$\omega_C = -k^\mu u^\mu|_{PC},$$

(22)

1 This fact is also taken into account by astronomers when reporting the corresponding total blue or red shifts since they subtract the contribution coming from the inclination of the galactic disc from the plane $\theta = \pi/2$. 

and the index $C$ refers to the emission ($e$) or detection ($d$) at the corresponding space-time point $P_C$. When the observer is comoving with the particle we have

$$\omega_e = -k_\mu u_\mu^e .$$

(23)

Thus, a photon emitted at point $P_C$ in the galactic plane possesses a 4-momentum $k^\mu_C = (k^t, k^\varphi, 0, k^r)_C$. The corresponding conserved quantities along the null geodesics of light signals read

$$E_\gamma = -g_{\mu\nu}\varepsilon^\mu k^\nu = -\left( g_{tt}k^t + g_{t\varphi}k^\varphi \right),$$

(24)

$$L_\gamma = g_{\mu\nu}\psi^\mu k^\nu = g_{\varphi\varphi}k^\varphi + g_{t\varphi}k^t ,$$

(25)

whereas the normalization condition for the 4-momentum $k^\mu k_\mu = 0$ is

$$0 = g_{tt}(k^t)^2 + g_{rr}(k^r)^2 + g_{\varphi\varphi}(k^\varphi)^2 + 2g_{t\varphi}k^tk^\varphi$$

(26)

and leads to the following expression for the $k^r$ in terms of the metric, the conserved quantities $L_\gamma, E_\gamma$, and $k^t$ and $k^\varphi$:

$$g_{rr}(k^r)^2 = E_\gamma k^t - L_\gamma k^\varphi = \frac{g_{\varphi\varphi}E_\gamma^2 + 2g_{t\varphi}E_\gamma L_\gamma + g_{tt}L_\gamma^2}{g^\varphi - g_{tt}g_{\varphi\varphi}} .$$

(27)

There are two frequency shifts which correspond to the maximum and minimum values of $\omega_e$ associated with light propagation in the same and the opposite direction of the motion of the signal emitter, in other words, the frequency shifts of a receding and an approaching star, respectively. As we shall see later, these max/min values of the frequency shifts are reached for stars whose position vector $\mathbf{r}$, with respect to the galactic center, is perpendicular to the detector’s line of sight, i.e., along the plane where $k^t = 0$ for the observer [2].

From the constant character along the geodesics of the product of the Killing vector field $\varepsilon^\mu$ with a geodesic tangent (24), together with the frequency definition (22) and taking into account that at $(r \to \infty)$, the 4-velocity of the detector is given by $u^\mu_d = (U^t, 0, 0, U^\varphi)_d$, we get the following expressions for the detector’s frequency

$$\omega_d = -k_\mu u^\mu_d = -\left( g_{tt}U^t k^t + g_{t\varphi}U^t k^\varphi + g_{\varphi\varphi}U^\varphi k^t + g_{t\varphi}U^\varphi k^\varphi \right) \bigg|_d$$

(28)

and the emitter’s frequency

$$\omega_e = -k_\mu u^\mu_e = -\left( g_{tt}U^t k^t + g_{t\varphi}U^t k^\varphi + g_{\varphi\varphi}U^\varphi k^t + g_{t\varphi}U^\varphi k^\varphi \right) \bigg|_e$$

(29)

Therefore, with the aid of the frequency shift (21) we have for arbitrary star orbits

$$1 + z = \frac{\omega_e}{\omega_d} \left( \frac{E_\gamma U^t - L_\gamma U^\varphi - g_{rr}U^r k^r}{E_\gamma U^t - L_\gamma U^\varphi} \right) \bigg|_e .$$

(30)

Since the star orbits we are considering are circular, then

$$1 + z = \frac{\omega_e}{\omega_d} \left( \frac{E_\gamma U^t - L_\gamma U^\varphi}{E_\gamma U^t - L_\gamma U^\varphi} \right) \bigg|_e = \frac{U^t_d - bU^\varphi_d}{U^t_d - bU^\varphi_d} ,$$

(31)
where we have introduced $b \equiv \frac{L}{E}$ – the impact parameter at infinity, and, hence, $|b|$ represents the radial distance at any side of the observed center of the galaxy, where $b = 0$. Since we shall consider red/blue shifts either side of the central value $b = 0$, it is convenient to express (31) as

$$1 + z_e = \left. \left( \frac{U^t - \epsilon |b| U^\varphi}{(U^t - \epsilon |b| U^\varphi)} \right) \right|_d,$$  \hspace{3cm} (32)

where $\epsilon = \pm 1$, and to compute the following quantity:

$$1 + z_c = \left. \left( \frac{U^t e}{U^t d} \right) \right|_d,$$  \hspace{3cm} (33)

where $L$ and $E$ are given by (13) and (17), respectively. This is the gravitational red shift of the center of the galaxy measured by an observer located at $r \rightarrow \infty$. Since in order to consider red/blue shifts either side of the central value $b = 0$, we need to subtract this quantity from (32), we define red and blue shifts as follows

$$Z_{\text{red}} = z_+ - z_c = \left. \left( \frac{U^t e e - U^t d d}{U^t d d - |b| U^t d d} \right) \right|_d,$$ \hspace{3cm} (34)

$$Z_{\text{blue}} = z_c - z_- = \left. \left( \frac{U^t e e - U^t d d}{U^t d d + |b| U^t d d} \right) \right|_d,$$ \hspace{3cm} (35)

corresponding to receding and approaching stars, respectively. It is obvious that now $Z_{\text{red}} \neq Z_{\text{blue}}$ (since $z_+ - z_c \neq z_c - z_-). These quantities are the general red and blue shifts, respectively, experimented by light signals traveling along null geodesics and emitted by circularly orbiting stars around the center of a galaxy to a distant observer. It is worth mentioning that in this formula we have dropped the gravitational red shift of the center of the galaxy, a fact that it is indeed taken into account by astronomers when reporting their observed data.

In the special case in which the detector is located “far away” enough from the source of information, i.e., if the contribution of the dragging of the detector’s inertial frame due to the rotation of the system, encoded in $U^\varphi_d$, is negligible in comparison to the contribution coming from the $U^t_d$ component, in other words, if $U^\varphi_d << U^t_d$, then the detector can be considered static at $r \rightarrow \infty$ and its 4-velocity will be given by $u^d_\mu = e^{2\Phi(\infty)} d^\mu_\nu$. This fact can be understood as well from the following analysis: since we are considering the limit in which $U^\varphi_d << U^t_d$, and taking into account that $u^d_\mu = \frac{d\varphi}{ds} |_d$ then

$$\frac{U^\varphi_d}{U^t_d} = \frac{d\varphi}{dt} = \Omega_d << 1,$$ \hspace{3cm} (36)

where $s$ is the proper time of the orbiting particle (star) and $\Omega_d$ is the angular velocity measured by the detector at $r \rightarrow \infty$.

Thus, in the special case in which $U^\varphi_d << U^t_d$ (or $\Omega_d << 1$,) the general red/blue shifts (34) and (35) reduce to the effective (quasi-static) red/blue shift defined by the following expression:

$$Z = \left. \left( \frac{U^\varphi_d}{U^t_d} |b| \right) \right|_d = -\left[ \frac{l}{r^2} + \left( \frac{E - LW}{c^2 + r^2} \right) \right]_d |b|,$$ \hspace{3cm} (37)
which is symmetric with respect to the center of the galaxy as in [1] and [2]. It is worth noticing that even when the dragging of the detector’s inertial frame is neglected, the differential rotation encoded in $W$, still plays a nontrivial role in the relation (36). Hence we have

$$Z^2 = \left. \frac{\left[ \frac{L}{R^2} + \frac{(E-LW)}{e^{2\Phi}} \right]^2}{\left( \frac{E-LW}{e^{2\Phi}} \right)_d} \right| e b^2 .$$

(38)

We further need to take into account the light bending due to the gravitational field generated by the rotating galaxy, in other words, we need to construct a mapping between the impact parameter $b$ and the location of the star $r$ given by its vector position with respect to the center of the galaxy, i.e., the mapping $b(r)$. Following [1] and [2], we shall choose the maximum value of $Z^2$ at a fixed distance from the observed center of the galaxy (at a fixed $b$). From (38) it follows that if the function factor that multiplies $b^2$ is monotone decreasing with increasing $r$, then the maximum observed value of $Z^2$ corresponds to the minimum value of $r$ along the null geodesic of the photons. This minimum value of $r$ corresponds to the position of the star either side of the center of the galaxy, lying on the plane perpendicular to the detector’s line of sight, i.e., on the plane where $k^r = 0$ for the observer located at $r \to \infty$. Thus, from (38) it follows that the squared impact parameter $b^2$ must also be maximized; this quantity can be calculated from the geodesic equation of the photons (or, equivalently, from the $k^\mu k_\mu = 0$ relation taking into account that $k^r = 0$) and is given by

$$b_\pm = -\frac{g_{t\varphi} \pm \sqrt{g_{t\varphi} - g_{tt}g_{\varphi\varphi}}}{g_{tt}}, \quad \text{hence} \quad b^2_\pm = \frac{\left( R^2 W \pm R e^\Phi \right)^2}{e^4 \Phi}.$$  

(39)

Since we look for the maximum value of $b$, then we should choose either $b_+$ or $b_-$, depending on the sign and magnitude of the product $R W$ with respect to $e^\Phi$, in such a way that $b$ is maximum. Finally, the monotone decreasing condition of the factor that multiplies $b^2$ in (38) imposes the following restriction

$$\left[ \ln \left( \frac{L}{R^2} + \frac{(E-LW)}{e^{2\Phi}} \right) \right]’ < \left[ \ln \left( \frac{E-LW}{e^{2\Phi}} \right) \right]_d’. \tag{40}$$

Thus, the mapping $b(r)$, responsible for the gravitational light bending, is given by (39) under the condition (40).

We should also mention here that the relations (39) and (40) reduce to the results obtained in [1] and [2] when $W = 0$ and $R = r$:

$$b^2 = \frac{r^2}{e^{2\Phi}} \quad \text{and} \quad \left( \ln \frac{L}{r^2} \right)’ < \left( \ln \frac{E}{e^{2\Phi}} \right)’,$$

(41)

respectively.

As mentioned above, observations are reported as

$$Z = v(b) - v(b = 0)$$  \tag{42}

where $Z$ is given by (38), supplemented by the light bending mapping (39).
3. Discussion
If one succeeds in determining the three unknown metric functions $\Phi$, $R$ and $W$ from observational data, this would imply that the dynamics of light signals is determined by the geodesics of a stationary axisymmetric metric, independently of the assumed dynamics of the geometry (of a concrete theory of gravitational interactions) or of the nature of dark matter, in the case that the latter is needed. However, the task of solving for $\Phi$, $R$ and $W$ is not trivial at all compared to the spherically symmetric case considered in [1] and [2] where there was just one unknown metric function to be determined.

A way of determining the above mentioned three arbitrary metric functions from observations consists in making use of the empiric Persic and Salucci’s universal formula for rotation curves in the halo region of a galaxy [8] (see also [30]):

$$Z_i = \frac{\alpha_i b^2}{b^2 + \beta_i},$$

(43)

where the constants $\alpha_i$ and $\beta_i$ correspond to the description of the central, red and blue shifts defined in (33)–(35) and labeled by the index $i$. These constants are determined from observations of a given galaxy.

An alternative way to proceed is to consider just the red and blue shifts, (34) and (35), related to this formula and make use of the relation (10) (or (11) if possible) in order to complete the system of equations for $\Phi$, $R$ and $W$. Thus, in principle, we can conform a system of three nonlinear differential equations of first order for three unknown metric functions. From the expressions found for the red/blue shifts it is obvious that the difficulties that arise in solving such a system are not trivial at all.

There is another kind of universal rotation curve formula for flat spiral galaxies that can be adjusted to observed data [31] and can be used to determine $\Phi$, $R$ and $W$ upon setting it to the red/blue shift language. Moreover, both of these universal rotation curve formulas could be used in a combined way in order to determine the metric functions $\Phi$, $R$ and $W$ from observations for one and the same sample of galaxies.

One more way to find these functions consists of approaching the galactic rotation curves problem in the post-Newtonian approximation in the spirit of [32], where the authors constructed analytical models that allow one to compute the first general relativistic corrections to the matter distributions and gravitational potentials for stationary systems with axial symmetry. It is worth mentioning that the main modifications in their approach appear far from the galaxy cores, a result that seems to be consistent with the predictions of [18]–[22].

We would like to point out as well that one can make a combined use of the red/blue shifts of galactic rotation curves and gravitational lensing as proposed in [33]–[34]. However, as stated in [34], till now the combined measured data come from different distance scales (red shifts): most high quality rotation curves are available for galaxies with a low to intermediate red shift of up to $z \sim 0.4$, while gravitational lenses are easier to detect at intermediate to high red shifts $z \gtrsim 0.4$. Therefore, both kinds of data are available for the same galaxy, but at different radii and, hence, they are not comparable. Thus, it is still difficult to take advantage from both sets of observations simultaneously. This situation will improve in the future when observations with a higher resolution will be carried out. In summary, more precise observational data are needed in order to benefit from the stationary axisymmetric approach to the galactic rotation curves problem within this context.

We should also mention that the presented stationary axisymmetric formalism can be applied to a wider range of astrophysical phenomena that leave the galactic framework like binary systems, accretion discs of rotating black holes and active galactic nuclei where the magnitude of the effects would be less restrictive compared to the galactic rotation curves. Some of these issues
are currently being pushed forward by the authors of this contribution and will be presented soon elsewhere.

Acknowledgments
The authors thank Pedro Colín and Daniel Sudarski for fruitful and illuminating discussions and SNI for partial financial support. AHA is also grateful to the Physics Department of UAM-I for hospitality and acknowledges support from the PAPIIT-UNAM grant No. IN103413-3 Teorías de Kaluza-Klein, inflación y perturbaciones gravitacionales. UN acknowledges support from the CIC–UMSNH Project No. 4.8 and PROMEP.
