A two-level medium, described by the Maxwell-Bloch (MB) system, is engraved by establishing a standing cavity wave with a linearly polarized electromagnetic field that drives the medium on both ends. A light pulse, polarized along the other direction, then scatters the medium and couples to the cavity standing wave by means of the population inversion density variations. We demonstrate that control of the applied amplitudes of the grating field allows to stop the light pulse and to make it move backward (eventually to drive it freely). A simplified limit model of the MB system with \textit{variable boundary driving} is obtained as a discrete nonlinear Schrödinger equation with \textit{tunable external potential}. It reproduces qualitatively the dynamics of the driven light pulse.

\textbf{Introduction.} Manipulation of light with light has become one of the hottest research spots in quantum optics this last decade. A widely studied field of research makes use of electromagnetically induced transparency in three-level systems, which allows to slow down, and eventually stop, a light pulse \cite{2}. Another interesting research option uses \textit{resonantly absorbing Bragg reflectors} (RABR) which consist in a periodic array of dielectric films separated by layers of a two-level medium \cite{3,4,5,6}, allowing a light pulse not only to be stopped and trapped \cite{7}, but also to be released by scattering with another control pulse, thus creating a \textit{“gap soliton memory”} \cite{8}.

The fundamental process underlying such novel light pulse dynamics is the cooperative action of nonlinearity and periodicity. Still, a serious drawback when making use of RABR is the built-in periodic structure that restricts both the freedom of pulse parameter and of pulse dynamics.

We propose to prepare a two-level system (TLS) by establishing a standing electromagnetic wave in a given polarization direction, and then to scatter a light pulse, orthogonally polarized. The incident pulse then feels the \textit{electromagnetic induced grating} through the coupling mediated by the population density, as described by the governing Maxwell-Bloch (MB) system \cite{3,4,5,6}. The freedom in the choice of the standing wave parameters (in particular the boundary amplitudes) allows us to demonstrate by numerical simulations as in Fig.\textsuperscript{4} that the incident light pulse not only can be stopped but also can be \textit{released back} to the incoming end. Engraving a medium with a cavity standing wave is a method previously used to create two dimensional waveguide arrays in strongly anisotropic photonic crystals \cite{11}.

In a TLS of transition frequency $\Omega$, the MB system is considered in the isotropic case for a plane polarized electromagnetic field propagating in direction $z$. The time is scaled to the inverse transition frequency $\Omega^{-1}$, the space $z$ to the length $\Omega c/\eta$ ($\eta$ is the optical index of the medium), the population inversion to the density of active dipoles $N_0$, the energy to the average $W_0 = N_0 \hbar \Omega/2$, the electric field to $\sqrt{W_0}/\varepsilon$ and the polarization to $\sqrt{\varepsilon W_0}$.

The resulting dimensionless MB system then reads

\begin{equation}
\begin{align*}
E_{tt} - E_{zz} + P_{tt} &= -\gamma E_t, \\
P_{tt} + P + \alpha N E &= -\gamma_2 P, \\
N_t - E \cdot P_t &= -\gamma_1 (1 + N).
\end{align*}
\end{equation}

where $E$ and $P$, denote vectors in the transverse plane, e.g. $E = (E_x(z,t), E_y(z,t))$. The coupling eventually results in a unique dimensionless fundamental constant $\alpha = 2 \mu_0 c^2/(3 \eta^2) \mu_{12}^2 N_0/\hbar \Omega (\eta^2 + 2)^2/9$ (where the dipole moment $\mu_{12}$ is averaged over the orientations \cite{10}) and by the normalization of the population inversion density: $N = -1$ when all active atoms are in the fundamental state, $N = 1$ in the excited state. The dimensionless dissipation coefficients are $\gamma = (c/\eta)(A/\Omega)$ resulting from the electric field attenuation $A$, then $\gamma_1 = 1/(\Omega T_1)$ and $\gamma_2 = 2/(\Omega T_2)$ resulting respectively from the population inversion dephasing time $T_1$ and the polarization dephasing time $T_2$.

In the strong coupling case $\alpha \sim 1$ (dense media), a multiscale analysis has shown that the model equation for the two directions of polarization results to be a system of coupled nonlinear Schrödinger equations \cite{12}. Then reduced to a unique polarization, it allows for slow light soliton formation out of evanescent incident light \cite{13}, namely under irradiation in the forbidden bang gap. This gap results from the linear dispersion relation of the MB system, for a carrier exp[$i(\omega t - k z)$] on a medium at rest, namely
\begin{equation}
\omega^2 (\omega^2 - \omega_0^2) = k^2 (\omega^2 - 1), \quad \omega_0^2 = 1 + \alpha,
\end{equation}

The upper edge of the stop gap at frequency $\omega_0$ corresponds to $k = 0$ and $d\omega/dk = 0$.

\textbf{Numerical simulations.} We first proceed with numerical simulations of the MB equations \cite{11} submitted to the
following boundary-value problem

\[ \mathbf{E}(0, t) = \begin{pmatrix} \mathcal{E}_1^{(0)} \cos(\omega_1 t) \\ \mathcal{E}_2^{(0)} \cos(\omega_2 t) \end{pmatrix}, \quad (3) \]

\[ \mathbf{E}(L, t) = \begin{pmatrix} \mathcal{E}_1^{(L)} \cos(\omega_1 t) \\ 0 \end{pmatrix}, \quad (4) \]

where \( \mathcal{E}_2(t) \) is the slowly-varying low-amplitude pulse envelope

\[ \mathcal{E}_2(t) = \frac{\mathcal{E}_{\text{max}}^{(0)}}{\cosh[\mu(t - t_0)]}. \quad (5) \]

The carrier frequencies are chosen close to the gap edge \( \omega_0 \), inside the passing band for the grating field, in the gap for the incident pulse, namely

\[ \omega_1 > \omega_0, \quad \omega_2 < \omega_0, \quad |\omega_j - \omega_0| \sim \mathcal{O}(\epsilon^2) \quad (6) \]

for \( j = 1, 2 \), where \( \epsilon \) is our small control parameter. We set from now on \( \alpha = 1 \).

To oscillate about the center \( z = 30 \). At time \( t = 4500 \) the left-hand-side amplitude \( \mathcal{E}_1^{(0)} \) is increased from 0.4 to 0.5, which produces the reverse motion of the stored pulse. Actually one may play with the driving amplitudes \( \mathcal{E}_1^{(0)} \) and \( \mathcal{E}_1^{(L)} \) to drive the pulse back and forth.

**Interpretation.** The process described above is now understood, within a multiscale analysis of MB equations, in terms of a discrete nonlinear Schrödinger model with variable coefficients related to the variation of the boundary grating field amplitudes. Thanks to (6), a solution of (1) under boundary values (3-4) can be sought under the form

\[ \mathbf{E}(z, t) = \begin{pmatrix} \epsilon E_1(\zeta, \tau_1) \\ \epsilon^2 E_2(\zeta, \tau_1, \tau_2) \end{pmatrix} e^{i\omega_0 t} + c.c. \quad (7) \]

with the slow variables \( \zeta = \epsilon z \) and \( \tau_n = \epsilon^{2n} t \). The second slow time \( \tau_2 \) is meant to capture the nonlinear dynamics of the low-amplitude (\( \epsilon^2 \)) long duration (\( \epsilon^{-2} \)) incident pulse. Note that form assumption (6), the frequency shift from \( \omega_0 \) is contained in the slow time variations with \( \tau_1 = \epsilon^2 t \).

Inserting then (7) in the MB system (1) we eventually obtain (with vanishing damping)

\[ \frac{\partial E_1}{\partial \tau_1} - \frac{\omega_0^2 - 1}{2 \omega_0^3} \frac{\partial^2 E_1}{\partial \zeta^2} - \frac{\omega_0^2 + 3}{4 \omega_0} |E_1|^2 E_1, \quad (8) \]

\[ \frac{i \partial E_2}{\partial \tau_1} - \frac{\omega_0^2 - 1}{2 \omega_0^3} \frac{\partial^2 E_2}{\partial \zeta^2} - \frac{\omega_0^2 + 1}{2 \omega_0} |E_1|^2 E_2 + \omega_0^2 \frac{E_1^* E_2}{4 \omega_0} e^{2^2 \left( -i \frac{\partial E_2}{\partial \tau_2} + \frac{\omega_0^2 + 3}{4 \omega_0} |E_2|^2 E_2 \right)}, \quad (9) \]

where star means complex conjugation. The boundary values (3-4) for the \( x \)-component \( E_1 \) imply from equation (8) that \( E_1(\zeta, \tau_1) \) is a periodic stationary solution of the nonlinear Schrödinger equation with frequency \( \nu_1 = (\omega_1 - \omega_0) e^{-2} \). It acts then as an external periodic potential in the evolution (9).

In order to take into account variations \( |E_1(\zeta)| \) resulting from the variations of the boundary driving (3) we set (remember \( \nu_1 \tau_1 = (\omega_1 - \omega_0) t \))

\[ E_1 = |E_1(\zeta)| e^{i\nu_1 \tau_1}, \quad |E_1|^2(\zeta) = V_0(\zeta) + \epsilon^2 V(\zeta) \quad (10) \]

where \( V_0(\zeta) \) is purely periodic while \( V(\zeta) \) describes the aperiodic inhomogeneities of \( |E_1(\zeta)| \) induced by the boundary values.

We then seek a solution of (10) on a suitable orthonormal basis of Wannier functions \( \varphi_j(\zeta) \) which are localized with respect to the site \( j \), within the one-band approximation (15), where \( j \) actually indexes the minima of the periodic potential \( V_0(\zeta) \). A solution of (10) is sought as

\[ E_2 = \sum_j e^{i\mu_j \tau_1} \mathcal{F}_j(\tau_1, \tau_2) \varphi_j(\zeta), \quad (11) \]
and the equation for the coefficients $F_j$ is worked out by inserting (11) in (10) and by projecting on a chosen $\varphi_j$. In the *tight-binding approximation* [16] we eventually obtain

$$
\begin{align*}
\frac{\partial F_j}{\partial \tau_1} - (\Omega_0 + \nu_1) F_j + \Lambda_0 F_j^* &= \epsilon^2 \left[ -i \frac{\partial F_j}{\partial \tau_2} + \Omega_j F_j \right. \\
&\left. - \Lambda_j F_j^* + Q (F_{j-1} + F_{j+1}) + U |F_j|^{2} F_j \right],
\end{align*}
$$

(12)

where the coefficients are given from the Wannier basis by (integrals run up $\zeta \in \mathbb{R}$)

$$
\begin{align*}
\Omega_0 &= \frac{\omega^2 - 1}{2\omega_0} \int \varphi_j'' \varphi_j + \frac{\omega^2 + 1}{2\omega_0} \int V_0 \varphi_j^2, \\
\Lambda_0 &= \frac{\omega^2 - 1}{4\omega_0} \int V_0 \varphi_j^2, \\
\Omega_j &= \frac{\omega^2 + 1}{2\omega_0} \int V \varphi_j^2, \quad \Lambda_j = \frac{\omega^2 - 1}{4\omega_0} \int V \varphi_j^2, \\
U &= \frac{\omega^2 + 3}{4\omega_0} \int \varphi_j^4, \quad \epsilon^2 Q = \frac{\omega^2 - 1}{2\omega_0} \int \varphi_j'' \varphi_j, \\
\end{align*}
$$

Note that translational invariance guarantees that the above coefficients are $j$-independent, except of course for $\Omega_j$ and $\Lambda_j$ that bear the aperiodic inhomogeneity of the external potential $|E_1|(|\zeta|)$.

Equation (12) can now be solved first for the $\tau_1$-dependence of $F_j$ as a linear system, which provides then a discrete nonlinear Schrödinger coupled system for the $\tau_2$-dependent amplitudes. This is done by seeking a solution under the form

$$
F = G^j_1 e^{-i \Delta \tau_1} + G^{-1}_j e^{i \Delta \tau_1}
$$

(13)

for which the leading order of (12) furnishes the two coupled linear equations

$$
\begin{align*}
- \left[ \Omega_0 + \nu_1 - \Delta \right] G^j_1 + \Lambda_0 (G^{-1}_j)^* &= 0, \\
- \left[ \Omega_0 + \nu_1 + \Delta \right] (G^{-1}_j)^* + \Lambda_0 G^j_1 &= 0,
\end{align*}
$$

The dispersion relation and the relation between $G^j_1$ and $(G^{-1}_j)^*$ automatically follows as

$$
\Delta = \sqrt{[\Omega_0 + \nu_1]^2 - \Lambda_0^2}, \quad (G^{-1}_j)^* = \frac{\Lambda_0}{\Omega_0 + \nu_1 + \Delta} G^j_1.
$$

At next order we readily get for $G_j^1$ the discrete nonlinear Schrödinger equation, the parameters of which are greatly simplified if we note that in our numerical simulations (for sufficiently deep lattice) $\Omega_0 \gg \Lambda_0$ and $\Omega_j \gg \Lambda_j$. In such a case the equation reads

$$
\begin{align*}
i \frac{\partial G^j_1}{\partial \tau_2} - \Omega_j G^j_1 &= Q [G^j_{j+1} + G^j_{j-1}] + U |G^j_2|^2 G^j_1.
\end{align*}
$$

(14)

The electric field envelope in the $y$-direction of polarization reads

$$
E_2 = \sum_j e^{-i \Omega_0 \tau_1} G^j_1 (\tau_2) \varphi_j (\zeta),
$$

(15)

in terms of the solution of the chosen Wannier basis.

The dynamics of the pulse is thus interpreted out of the discrete nonlinear Schrödinger model (14) as the action of the potential $\Omega_j$ that translates the applied variations of the boundary driving in the $x$-direction of polarization.

**Application.** In order to illustrate the above interpretation, we proceed now with numerical simulations of (14) where $\tau_2 = t$ to read quantities in physical dimensions. The potential $\Omega_j$ models the variations of $|E_1|$ away from a purely periodic function as soon as $\epsilon^{(0)}_1 \neq \epsilon^{(L)}_1$. We set

$$
\Omega_j = \begin{cases}
0 & , \ t < 650, \\
-0.07 j & , \ t > 650
\end{cases}
$$

(16)

and obtain the Fig.2 which shows the same qualitative behavior as Fig.1.

**Conclusion and comments.** We have shown that the Maxwell-Bloch system, the celebrated fundamental and general semi-classical model of interaction of radiation with matter, may serve as a tool to store and manipulate light pulses in an arbitrary way by conveniently using laser light to engrave the medium with a controllable standing wave pattern. The extreme genericity of MB model together with the freedom in the boundary values of the engraving field, constitute a decisive advantage over other techniques to store and manipulate light pulses.

The process is understood by deriving a discrete nonlinear Schrödinger model where the external tunable potential actually translates the effects of boundary driving variations. Our purpose was simply to provide a *qualitative* interpretation.

A more detailed study, reported to future work, would require first to use exact solutions of (13) for the grating...
field (e.g. in terms of Jacobi elliptic functions), second to construct the corresponding most adequate Wannier basis, third to evaluate precisely the effect of boundary driving variations on the factor $\Omega_j$, and last to study the full system (12) that couples $\mathcal{F}_j$ to $\mathcal{F}_j^\ast$.
