Abstract
We continue our exploration of the collective modes of an anisotropic quark gluon plasma by extending our previous analysis to arbitrary Riemann sheets. We demonstrate that in the presence of momentum-space anisotropies in the parton distribution functions there are new relevant singularities on the neighboring unphysical sheets. We then show that for sufficiently strong anisotropies that these singularities move into the region of spacelike momentum and their effect can extend down to the physical sheet. In order to demonstrate this explicitly we consider the polarization tensor for gluons propagating parallel to the anisotropy direction. We derive analytic expressions for the gluon structure functions in this case and then analytically continue them to unphysical Riemann sheets. Using the resulting analytic continuations we numerically determine the position of the unphysical singularities. We then show that in the limit of infinite contraction of the distribution function along the anisotropy direction that the unphysical singularities move onto the physical sheet and result in real spacelike modes at large momenta for all “out-of-plane” angles of propagation.

I. INTRODUCTION

The ultrarelativistic heavy ion collision experiments ongoing at the Brookhaven Relativistic Heavy Ion Collider (RHIC) and planned at the CERN Large Hadron Collider (LHC) will study the behavior of nuclear matter under extreme conditions. Specifically, these experiments will explore the QCD phase diagram at large temperatures and small quark chemical potentials. Based on the data currently available from the RHIC collisions it seems that a thermalized state has been created during the collisions [1]. Remarkably it seems that the thermalization proceeds rather rapidly in contradiction to estimates from leading order equilibrium perturbation theory. However, to truly understand how the plasma evolves and thermalizes one has to go beyond the equilibrium description. In this paper we expand upon our previous studies of the collective modes of a quark gluon plasma which is (at least approximately) homogeneous and stationary but anisotropic in momentum space.

These types of distribution functions are relevant because of the approximate longitudinal boost invariance in the central rapidity region of ultrarelativistic heavy ion collisions. This implies that the initial distribution functions for the partons are practically delta functions in longitudinal momentum. Such an anisotropic quark-gluon plasma appears to be qualitatively different from the isotropic one since the quasiparticle collective modes can then be unstable [2, 3, 4, 5, 6, 7, 8, 9, 10]. The presence of these instabilities can dramatically influence the system’s evolution leading, in particular, to its faster equilibration and isotropization. Treating this problem in all of its generality is a daunting task. In order to make progress we consider the limit of very high transverse temperatures at which the non-equilibrium collective behavior is describable in terms of processes in which all loop momenta are hard. In the case of thermal equilibrium hard corresponds to momenta of order $T$ but in the non-equilibrium case hard corresponds to an unspecified scale contained in the distribution function.

In a previous paper [7] we calculated the hard-loop gluon polarization tensor in the case that the momentum space anisotropy is obtained from an isotropic distribution by the rescaling of one direction in momentum space. The resulting expression for the gluon polarization tensor was then decomposed into a four-component tensor basis and the structure functions associated with this tensor basis where computed numerically for general anisotropies and analytically in the limit of small anisotropies. We demonstrated that a contraction of an isotropic distribution function along the anisotropy direction, $\hat{n}$, resulted in one additional stable quasiparticle mode, two damped quasiparticle modes in the lower half plane, and two unstable (anti-damped) quasiparticle modes in the upper half plane. In the case that the isotropic distribution was stretched along the anisotropy direction we found that again an additional stable quasiparticle mode was generated but only one damped and one anti-damped quasiparticle mode were found in this case. The unstable modes found correspond to electric or magnetic type instabilities with the latter being analogous to the Weibel instability in QED plasmas [11, 12, 13, 14, 15].

In this paper we continue our exploration of the collective modes of an anisotropic quark gluon plasma by extending our previous analysis to arbitrary Riemann sheets. We demonstrate that in the presence of momentum-space anisotropies in the parton distribution functions there are new relevant singularities on the neighboring unphysical sheets. We then show that for sufficiently strong anisotropies that these singularities move into the region of spacelike momentum and their effect can extend down to the physical sheet. In order to demonstrate this explicitly we consider the polarization tensor for gluons propagating parallel to the anisotropy direction. We derive analytic expressions for the gluon structure functions in this case and then analytically continue them to
unphysical Riemann sheets. Using the resulting analytic continuations we numerically determine the position of the unphysical singularities. We then show that in the limit of infinite contraction of the distribution function along the anisotropy direction that the unphysical singularities move onto the physical sheet and result in real spacelike modes at large momenta for all “out-of-plane” angles of propagation.

The organization of the paper is as follows: In Sec. II we first review the necessary integral expressions for the hard-loop gluon polarization tensor and then in Sec. III we present analytic expressions for the hard-loop gluon polarization tensor structure functions in the case that the gluon is propagating parallel to the anisotropy direction. In Secs. III A-III D we extend these expressions to arbitrary Riemann sheets and solve the dispersion relations for the singularities existing on the neighboring unphysical sheets. In Sec. IV we present analytic expressions for the gluon polarization tensor structure functions in the large-anisotropy limit and solve the resulting dispersion relations for arbitrary angle of propagation. In Sec. V we summarize the results and speculate about the possible impact of the now relevant unphysical singularities.

II. GLUON POLARIZATION TENSOR REVISITED

The hard-loop gluon polarization tensor of an anisotropic system is given by

\[ \Pi^{ij}(K) = -2\pi\alpha_s \int \frac{d^3p}{(2\pi)^3} v^i \partial^j f(p) \left( \delta^{jl} + \frac{v^j k^l}{K \cdot V + i\epsilon} \right), \]

where \( K = (\omega, k), \) \( V = (1, v), \) \( v = p/|p| \) and

\[ f(p) = f_\xi(p) = N(\xi) f_{iso} \left( \sqrt{p^2 + \xi (p \cdot \hat{n})^2} \right). \]

Note that in Sec. II we have specialized to spacelike Lorentz indices; however, it is possible to derive the polarization tensor also for arbitrary Lorentz indices.

To simplify the calculation we follow Ref. and require the distribution function \( f(p) \) to be given by

\[ f(p) = f_\xi(p) = N(\xi) f_{iso} \left( \sqrt{p^2 + \xi (p \cdot \hat{n})^2} \right). \]

Here \( f_{iso} \) is an arbitrary isotropic distribution function, \( \hat{n} \) is the direction of the anisotropy, \( \xi > -1 \) is a parameter reflecting the strength of the anisotropy, and \( N(\xi) \) is a normalization constant. To fix \( N(\xi) \) we require that the number density to be the same both for isotropic and arbitrary anisotropic systems,

\[ \int_p f_{iso}(p) = \int_p f_\xi(p) = N(\xi) \int_p f_{iso} \left( \sqrt{p^2 + \xi (p \cdot \hat{n})^2} \right), \]

and can be evaluated to be

\[ N(\xi) = \sqrt{1 + \xi}. \]

Using an appropriate tensor basis one can then decompose the self-energy into four structure functions \( \alpha, \beta, \gamma, \) and \( \delta \) by taking the contractions

\[ k^i \Pi^{ij} k^j = k^2 \beta, \]
\[ \bar{n}^i \Pi^{ij} k^j = \bar{n}^2 k^2 \delta, \]
\[ \bar{n}^i \Pi^{ij} \bar{n}^j = \bar{n}^2 (\alpha + \gamma), \]
\[ \text{Tr} \Pi^{ij} = 2\alpha + \beta + \gamma. \]
where $\tilde{n}^i = (\delta^{ij} - k^i k^j / k^2) n^j$. The structure functions then depend on $\omega, k$ and the angle $\hat{k} \cdot \hat{n} = \cos \theta_n$ as well as on the strength of the anisotropy, $\xi$. Integral expressions for $\alpha, \beta, \gamma,$ and $\delta$ for arbitrary angle of propagation and anisotropy parameter $\xi$ can be found in Ref. [7].

III. SPECIAL CASE I : $k || \hat{n}$

Let us now consider the case where the momentum $k$ is in the direction of the anisotropy, $\hat{n}$, i.e. $\theta_n = 0$. Using the changes of variables

$$\tilde{p}^2 = p^2 \left( 1 + \xi (v \cdot \hat{n})^2 \right),$$

allows us to simplify Eq. (11) to

$$\Pi^{ij}(K) = m_D^2 \sqrt{1 + \xi} \int \frac{d\Omega}{4\pi} \frac{v^l + \xi (v \cdot \hat{n}) \tilde{n}^l}{(1 + \xi (v \cdot \hat{n})^2)^2} \left( \delta^{ij} + \frac{v^i k^j}{K \cdot V + i\epsilon} \right),$$

where

$$m_D^2 = -\frac{\alpha_s}{\pi} \int_0^\infty dp \frac{d^4 f_{iso}(p^2)}{dp}.$$ (9)

Taking the contractions in Eq. (6) the structure functions can further be simplified using

$$k \cdot v = k \hat{n} \cdot v = k \cos \theta.$$ (10)

While one integration becomes straightforward, the remaining integration can be performed after a little bit of algebra and one obtains for the relevant contractions

$$\frac{\alpha}{m_D^2} = \frac{\sqrt{1 + \xi}}{4\sqrt{\xi}(1 + \xi z^2)^2} \left[ (1 + z^2 + \xi (-1 + (6 + \xi) z^2 - (1 - \xi) z^4) - \arctan \sqrt{\xi}
+ \sqrt{\xi} \left( (z^2 - 1)(1 + \xi z^2 - (1 + \xi) z \ln \frac{z + 1 + i\epsilon}{z - 1 + i\epsilon} \right) \right],$$

$$\frac{\beta}{m_D^2} = -\frac{z^2 \sqrt{1 + \xi}}{2\sqrt{\xi}(1 + \xi z^2)^2} \left[ (1 + \xi)(1 - \xi z^2) \arctan \sqrt{\xi}
+ \sqrt{\xi} \left( (1 + \xi z^2) - (1 + \xi) z \ln \frac{z + 1 + i\epsilon}{z - 1 + i\epsilon} \right) \right],$$

$$\frac{\hat{\delta}}{m_D^2} = \frac{z \sqrt{1 + \xi}}{4\sqrt{\xi}(1 + \xi z^2)^3} \left[ z \left( -1 + \xi (3 + 6 \xi - 2(3 + 6 \xi + \xi^2) z^2 + \xi (3 + \xi) z^4) \right) \arctan \sqrt{\xi}
+ \sqrt{\xi} \left( (1 + \xi z^2)(1 + 4 \xi - 3 \xi z^2) + \xi (-1 + z^2)(-1 + 4 z^2 + 3 \xi z^2) \ln \frac{z + 1 + i\epsilon}{z - 1 + i\epsilon} \right) \right],$$ (11)

where $z = \omega/k$ and $\hat{\delta} = \delta k$. Note that for this angle of propagation the structure function $\gamma$ vanishes.

A. Extension to unphysical sheets

The above structure functions all possess a logarithmic cut running along the real $z$ axis for $z^2 < 1$. It is, however, possible to extend their definition beyond this cut, which then corresponds

In Ref. [7] $N(\xi)$ was fixed to be $N(\xi) = 1$ so the reader should make sure to adjust for the difference where appropriate.
to an unphysical Riemann sheet of $z$. More precisely, there are two such unphysical sheets which can be accessed by either extending the physical sheet from above or below the cut. In order to make this extension we first compute the structure functions on the physical sheet using the integral representation given in Eq. (8). We can then deform the integration contour which runs from $\cos \theta = -1$ along the real axis to $\cos \theta = 1$ into the lower half plane (LHP) and then move the point we are interested in from the upper to the lower half plane. Deforming the original contour so that it again runs along the real axis we see that we pick up an extra contribution corresponding to the residue at the point in the LHP.

This procedure can be used to analytically continue the structure functions for all values of $\theta_n$ but in the case that $\theta_n = 0$ the residue can be evaluated straightforwardly and is simply $-2\pi i$. The structure functions can likewise be extended into the upper half plane (UHP) and the residue is then $+2\pi i$. The resulting rule is then the expected one, namely, that the structure functions can be extended to unphysical sheets by the usual extension of the logarithm

$$\ln \left( \frac{z + 1}{z - 1} \right) = \ln \left( \left| \frac{z + 1}{z - 1} \right| \right) + i \left[ \arg \left( \frac{z + 1}{z - 1} \right) + 2\pi n \right] , \quad (12)$$

where $n$ specifies the sheet number. Note that $n = 1$ extends the physical logarithm into the UHP and $n = -1$ extends it into the LHP. Higher $n$ correspond to higher sheets which can be safely ignored as we will discuss below.

**B. Collective modes**

The dispersion relations for the gluonic modes in an anisotropic quark-gluon plasma are in general given by the zeros of

$$\Delta^{-1}_A = k^2 - \omega^2 + \alpha = 0 ,$$

$$\Delta^{-1}_G = (k^2 - \omega^2 + \alpha + \gamma)(\beta - \omega^2) - k^2 \hat{n}^2 \delta^2 = 0 . \quad (13)$$

In the case $k||\hat{n}$, however, $\gamma$ vanishes identically, as does $\hat{n}^2 = 1 - (\hat{k} \cdot \hat{n})^2$. Therefore, it is sufficient to solve the equations

$$k^2 - \omega^2 + \alpha = 0 ,$$

$$\beta - \omega^2 = 0 , \quad (14)$$

which will be referred to as $\alpha$- and $\beta$-modes, respectively. These modes correspond to poles in the propagator for $\alpha$- and $\beta$-modes. We will use this term to describe solutions on both physical and unphysical Riemann sheets; however, whenever we are speaking about the unphysical singularities we will always explicitly label them as *unphysical* $\alpha$- and $\beta$-modes. The reader should be aware that these unphysical singularities do not correspond to real degrees of freedom unless the solution associated with them moves onto the physical Riemann sheet.

Before we present the dispersion relations we would like to first count the number of modes on the various sheets in order to be assured that we have indeed found all solutions. The number of modes can be counted by doing a so-called Nyquist analysis, based on the special case of Cauchy’s integral,

$$N - P = \frac{1}{2\pi i} \oint_C dz \frac{f'(z)}{f(z)} , \quad (15)$$

where $N$ and $P$ are the number of zeros and poles of $f(z)$ times their multiplicity in the region encircled by the closed path $C$. 

5
Choosing \( f(z) = k^2(1 - z^2) + \alpha(z) \) and using the explicit form of the structure function given in Eq. (11), one finds that \( f(z) \) has a logarithmic cut for real \( z^2 < 1 \), while being analytic for all other finite \( z \). One can then choose the contour \( C \) depicted in Fig. 1 so that \( P = 0 \). We then evaluate the respective pieces of the contour \( C \), finding

\[
N_{\alpha,\text{phys}} = \frac{1}{2\pi i} \left( 4\pi i + 0 + 4\pi i \Theta (-\lim_{z \to 0} f(z)) \right) = 2 + 2\Theta (-\lim_{z \to 0} f(z)) .
\]

The first contribution comes from the large circle at \( |z| \gg 1 \), while the first zero is the contribution from the path connecting the large circle with the contour around \( z^2 < 1 \); the second zero is the contribution from the small half-circles around \( z = \pm 1 \). The last contribution comes from the straight lines running infinitesimally above and below the cut at \( z^2 < 1 \). They can be evaluated by using

\[
\int_{-1+\epsilon}^{1+\epsilon} \frac{dz}{f(z)} = \ln \frac{f(1 + i\epsilon)}{f(-1 + i\epsilon)} ,
\]

and therefore represent the “winding number” of the image of \( f(z) \) around the origin. Since from Eq. (11) it is clear that \( \text{Re} f(-1 + i\epsilon) > 0 \) and for \( z^2 < 1 \) one has \( \text{Im} f(z) = 0 \) only for \( z = 0 \), the winding number can either be zero or one, depending on the sign of \( \lim_{z \to 0} \text{Re} f(z + i\epsilon) \). For the path with \( \text{Im} z < 0 \) one proceeds similarly, finding the result given in Eq. (16).

For the \( \beta \)-mode, the same techniques can be applied to find the result

\[
N_{\beta,\text{phys}} = 2.
\]

These two modes, together with two modes coming from \( N_{\alpha,\text{phys}} \), correspond to the propagating and stable modes for positive and negative (real) frequencies, while the modes that depend on the sign of the static limit of \( f(z) \) correspond to solutions with purely imaginary \( z \) which are the damped and anti-damped physical modes already found in Ref. [7].

We now want to extend the above analysis to the unphysical sheets that can be accessed by extending the structure functions through the cut to the LHP and UHP, as discussed above. Let us first discuss the \( \alpha \)-mode in the unphysical LHP by introducing \( f_{LHP}(z) = k^2(1 - z^2) + \alpha_{LHP}(z) \) and choosing a contour \( C_{LHP} \) which is shown in Fig. 2. One notable difference to the physical
FIG. 3: Dispersion relations for the unphysical $\alpha$-modes for $\theta_n = 0$ and (a) $\xi = 0.1$, (b) $\xi = 1$, and (c) $\xi = 10$. Dotted lines correspond to the modes which depend on the sign of $f_{LHP}$ (type-1). Note that in (a), (b), and (c) the type-1 unphysical $\alpha$-mode only exists for $k > 0.184$, $k > 0.595$, and $k > 1.95$, respectively. Dashed lines correspond to modes which do not depend on the sign of $f_{LHP}$ (type-2). Solid line in (a) is the isotropic result. Note that the scale changes in each plot.
Note, however, that the second term in Eq. (21) indicates the presence of unstable modes on the physical sheet for this angle of propagation and, as a result, the isotropic and anisotropic dispersion relations for the unphysical \(\alpha\)-modes are not trivially connected. This is demonstrated by the fact that the type-1 mode (dotted lines) in Fig. 3 do not extend down to \(k = 0\) for finite \(\xi\) but instead terminate at a finite \(k = k_0\). Below \(k_0\) the type-1 mode in the LHP moves onto the physical sheet and becomes the unstable (anti-damped) physical \(\alpha\)-mode already discussed in Ref. 7. The type-1 mode in the UHP likewise moves onto the physical sheet and becomes the damped physical \(\alpha\)-mode solution.

A plot of the dispersion relations of the physical and unphysical \(\beta\)-modes for \(\xi = 10\) is shown in Fig. 4 (the mirror region \(\text{Re} \ z < 0\) is not shown). As one can see, the unphysical \(\beta_{\text{LHP/UHP}}\) mode is lightlike for small momentum and spacelike at large momentum. As we will discuss below this mode is physically relevant if \(\text{Re} \ z\) is approximately spacelike, \((\text{Re} \ z)^2 \lesssim 1\), and the modulus of \(\text{Im} \ z\) is small. In addition, in Fig. 5 we have plotted the position of the unphysical \(\beta\)-mode pole for momentum \(k = \{m_D/2, m_D, 2m_D\}\) in the complex plane for various values of \(\xi\).

From Fig. 5 we see that, as the anisotropy is decreased the \(\text{Im} \ z\) of the unphysical \(\beta\)-mode becomes large at all momentum and therefore these unphysical modes will have a negligible impact on the propagator on the physical Riemann sheet. However, as the anisotropy is increased with fixed momentum, the modulus of \(\text{Im} \ z\) decreases so that these modes can become relevant for large anisotropies. From Fig. 5 we can also see that for fixed \(\xi\) and decreasing \(k\) that the unphysical \(\beta\)-modes move to \(z = \infty\) and so are unimportant based on the criteria stated above. However, for \(k \gtrsim m_D\) the unphysical \(\beta\)-modes have \((\text{Re} \ z)^2 \lesssim 1\). Therefore for large anisotropies and \(k \gtrsim m_D\) the effects of the unphysical \(\beta\)-modes can have an important impact on the propagator for spacelike modes on the physical Riemann sheet. Additionally, we see that for infinite \(\xi\) the \(\text{Im} \ z\) of the unphysical \(\beta\)-mode vanishes and it then moves to the physical sheet as we will discuss below.
FIG. 6: Sketch of the complex $z$ plane including the extension of the logarithm to the unphysical sheet. Also shown is how a pole in the unphysical region (mountain) has effects felt on the physical sheet. The black line indicates where the two sheets are joined together.

FIG. 7: Dispersion relations for $\theta_n = 0$ and $\xi = 10^4$: the $\beta$-mode approaches its large-$\xi$ behavior. Again the physical $\alpha$-, physical $\beta$-, and unphysical $\beta$-modes are indicated by dashed, solid, and dotted lines, respectively.

C. Mountains on spirals

As discussed in the previous section we find that, in addition to modes on the physical sheet found in Ref. [7], for anisotropic systems there are also unphysical $\alpha$- and $\beta$-modes on neighboring Riemann sheets. But why bother about these modes, given that they do not “live” on the physical sheet? To see that there can be an effect on physical quantities, imagine the structure of the complex $z$ plane spanned by the different sheets of the logarithm in the form of a spiral staircase: the physical sheet would correspond to the region covered by the spiral plane from the ground floor to the first floor, while the unphysical sheet where the extra quasiparticle mode lives would correspond to the region first to second floor.

However, since for a range of momenta the unphysical $\beta$-mode corresponds to an approximately spacelike pole, the propagator has a mountainous dent (singularity) in the spiral plane somewhere from the first to the second floor, with its peak the nearer the first floor the larger $\xi$ is. But because the mountain has a finite width, its base can be felt also below the second floor, especially if its peak is near the first floor (see Fig. 6 for a sketch). This is precisely the situation we presented in previous section. There we showed that in the large-$\xi$ limit that for $k \gtrsim m_D$ the $\text{Im } z$ of the unphysical $\beta$-modes becomes very small and $(\text{Re } z)^2 \lesssim 1$. Therefore, we expect that the unphysical modes on neighboring Riemann sheets do have physical consequences for large anisotropies, since then their effect can extend down to the physical sheet. In fact, as we will discuss below, in the limit of infinite $\xi$ the pole moves onto the physical sheet itself. Note that the physical effect of any singularities existing on higher Riemann sheets ($|m| > 1$) would be negligible since the effect of these singularities would have to extend through the intermediate sheets prior to getting to the physical sheet, i.e. the base of the mountain would have to extend all the way down to the physical sheet through the spacelike spirals.
D. Towards large $\xi$

For very large values of $\xi$, the dispersion relations are shown in Fig. 7. As one can see, the physical $\beta$-mode now hits the lightcone at the point where the unphysical mode becomes spacelike. Indeed, when one takes the limit of $\xi \to \infty$, the $\beta$-mode simply becomes

$$1 - \frac{\pi m_D^2}{4 \omega^2} = 0,$$

which has the simple real and propagating solution $\omega^2 = \pi m_D^2 / 4$. For any finite $\xi$ the logarithmic singularity of $\beta$ in Eq. (11) at the lightcone causes the physical $\beta$-mode to always be timelike; however, the unphysical solution exists for both timelike and spacelike momenta.

IV. SPECIAL CASE II: $\xi \to \infty$

Another special case where one can explicitly calculate the structure functions is when $\xi \to \infty$. In this case it has been found in Ref. [9] that the distribution function becomes

$$\lim_{\xi \to \infty} f_\xi(p) \to \delta(\hat{p} \cdot \hat{n}) \int_{-\infty}^{\infty} dx f_{\text{iso}}(p\sqrt{1 + x^2}),$$

which corresponds to the extreme anisotropic case considered by Arnold, Lenaghan, and Moore [8]. As a consequence, one can make use of this form by partially integrating Eq. (1) to obtain

$$\Pi^{ij}(K) = 2\pi \alpha_s \int \frac{d^3 p}{(2\pi)^3} \frac{f_\xi(p)}{p} \left[ \delta^{ij} - \frac{k^i v^j + k^j v^i}{-K \cdot V - i\epsilon} \right],$$

and applying the techniques from Ref. [8] to obtain analytic expressions for the structure functions in the large-$\xi$ limit. Using

$$\lim_{\xi \to \infty} 2\pi \alpha_s \int \frac{d^3 p}{(2\pi)^3} \frac{f_\xi(p)}{p} = m_D^2 \frac{\pi}{4},$$

the structure functions are obtained using the contractions Eq. (6), giving

$$\alpha = \frac{m_D^2 \pi}{4} \left[ -\cot^2 \theta_n + \frac{z}{\sin^2 \theta_n} \left( z \pm \frac{1 - z^2}{\sqrt{z + \sin \theta_n} \sqrt{z - \sin \theta_n}} \right) \right],$$

$$\beta = \frac{m_D^2 \pi}{4} z^2 \left[ -1 \pm \frac{z^2 + \cos 2\theta_n}{(z + \sin \theta_n)^{3/2} (z - \sin \theta_n)^{3/2}} \right],$$

$$\gamma = \frac{m_D^2 \pi}{4} \frac{1 - z^2}{4 \sin^2 \theta_n} \left[ 6 + 2 \cos 2\theta_n \pm \frac{3 - 6z^2 - 2(1 + z^2) \cos 2\theta_n - \cos 4\theta_n}{(z + \sin \theta_n)^{3/2} (z - \sin \theta_n)^{3/2}} \right],$$

$$\hat{\delta} = \frac{m_D^2 \pi}{4} \frac{\cos \theta_n}{\sin^2 \theta_n} \left[ z \pm \frac{(1 - 2z^2) \cos^2 \theta_n - (1 - z^2)^2}{(z + \sin \theta_n)^{3/2} (z - \sin \theta_n)^{3/2}} \right].$$

(27)

where a positive sign above corresponds to the physical sheet and a negative sign corresponds to the unphysical sheet. Note that the lightcone singularity at $z^2 = 1$ is not present in these structure functions any longer. In fact, all structure functions turn out to be purely real for $z^2 > \sin^2 \theta$ while there is a singularity located at $z^2 = \sin^2 \theta$. Below this lightcone-like structure, the imaginary parts are non-vanishing.
FIG. 8: Dispersion relations for $\xi = \infty$ for (a) $\theta_n = \frac{\pi}{4}$ and (b) $\theta_n = \frac{\pi}{2}$. Shown are the physical $\alpha-$ mode (short dashed lines) and the two physical $\beta$-modes (full and dotted lines) as well as the unphysical $\beta$-mode (long-dashed lines), respectively. For $\theta_n = 0$, the dispersion relations resemble those of Fig. 7 except that the mode which follows the light cone beyond $k^2 = m_D \pi/4$ in Fig. 7 ceases to exist and the $\beta$-mode connects continuously across the lightcone to the now physical spacelike mode.

A. Collective modes

The dispersion relations of the collective modes are once more determined by the zeros of Eq. (13). By conducting a Nyquist analysis similar to the previous section, one finds $N_{\alpha, \text{phys}} = 2 + 2\Theta (\lim_{z \to 0} \Delta_A(z))$ and $N_{\Delta_G, \text{phys}} = 4 + 2\Theta (\lim_{z \to 0} \Delta_G(z))$ for the physical sheet. These modes can be identified as the standard, propagating modes (one for $\Delta_A$ and two for $\Delta_G$ together with their negative frequency equivalents) as well as two imaginary modes (one in the UHP and one in LHP) for $\Delta_A$ and $\Delta_G$, respectively. The latter again depend only on the sign of the static limit of the propagators, which in the limit of large $\xi$ are functions of the momentum $k$ and the angle $\theta_n$, respectively.\(^2\)

By once again extending the structure functions Eq. (27) to the unphysical sheets in the LHP and UHP (the terms involving square roots simply pick up an overall minus sign) we are also able to count the modes there by repeating the earlier analysis. One finds $N_{\alpha, \text{LHP}} = N_{\alpha, \text{UHP}} = \Theta (\lim_{z \to 0} \Delta_A(z))$ corresponding to a purely imaginary mode, and $N_{\Delta_G, \text{LHP}} = N_{\Delta_G, \text{UHP}} = 2 - \Theta (\lim_{z \to 0} \Delta_G(z))$. The first two of the latter modes are in general complex modes but may – in some restricted region of parameter space – also become purely imaginary solutions; the step function then just encodes the fact that one of the purely imaginary solutions moves to the physical sheet.

V. CONCLUSIONS

In this paper we have extended our studied the gluon polarization tensor in an anisotropic system. We extended our previous analysis to unphysical Riemann sheets and showed that for anisotropic distribution functions there are modes (singularities) in the “spacelike region” of the unphysical sheet which become physically relevant for large anisotropies. The chief way that these...
modes affect the physics by altering the behavior of the propagator at soft spacelike momenta. The behavior of the propagator in this region determines the rate of energy transfer from soft to hard modes and the sign of this energy transfer may change for anisotropic systems so that there is instead a transfer of energy from hard to soft modes \[16\]. Whether or not the presence of the modes on the unphysical Riemann sheets are responsible for this “anti-Landau-damping” will be investigated in a separate paper \[17\] in which we compute heavy fermion energy loss in a quark-gluon plasma along the lines of Ref. \[18\] in which we calculated the same in an anisotropic QED plasma.

In addition to these unphysical \(\beta\)-modes we found that for anisotropic distributions the unphysical \(\alpha\)-modes are different than in the isotropic case. In the isotropic case, there are two unphysical \(\alpha\)-modes with one being in the upper half plane of the \(n = 1\) unphysical sheet and one in the lower half plane of the \(n = -1\) unphysical sheet. We showed that for finite-\(\xi\) and small momentum these isotropic unphysical modes move onto the physical sheet and become the unstable modes already discussed in Ref. \[7\]. Additionally, for finite anisotropy there are two additional unphysical \(\alpha\)-modes, again, with one being in the upper half plane and one in the lower half plane. These modes would, in principle, determine the dynamic screening of the magnetic gluon interaction at small momentum; however, the instabilities in this region will dominate the physics so it’s not entirely obvious how important these additional unphysical \(\alpha\)-modes are.

In closing we would like to point out that although the finite-\(\xi\) analysis presented here was performed only for \(\theta_n = 0\) there are generally relevant unphysical \(\alpha\)- and \(\beta\)-modes for all angles of propagation. The analysis proceeds exactly as discussed here but the details (number of modes etc.) changes here and there. Additionally, the results presented here are also applicable to anisotropic ultrarelativistic QED plasmas.

Acknowledgments

The authors would like to that A. Rebhan for very useful discussions and feedback. M.S. was supported by the Austrian Science Fund Project No. M790-N08.
