Abstract. We calculate the thermochemical equilibrium of the diffuse interstellar medium, including ionization by a photon flux $F_\nu$ from neutrino decay. The main heating mechanism considered is photoelectrons from grains and PAHs. For the studied range of $F_\nu$ values, there always exists two regions of stability (a warm and a cold phase) that can coexist in equilibrium if the thermal interstellar pressure is between a maximum value ($P_{\text{max}}$) and a minimum value ($P_{\text{min}}$). High $F_\nu$ values ($\sim 10^4 - 10^5 \text{ cm}^{-2} \text{s}^{-1}$) can be consistent with observed interstellar pressures only if more efficient sources are heating the gas. It is shown that a neutrino flux increase (due, for example, to an increase in the supernova explosion rate) may stimulate the condensation of cold gas by decreasing $P_{\text{max}}$ below the interstellar pressure value.

Key words: ISM: general – ISM: clouds – stars: formation – elementary particles

1. Introduction

The diffuse interstellar medium (ISM) is observed to be inhomogeneous with cold ($T \lesssim 10^2 \text{ K}$) clouds embedded in a warmer ($T \sim 10^4 \text{ K}$) intercloud gas (see, for example, the review of Kulkarni & Heiles 1988). The theoretical explanation for this structure was provided by Field et al. (1969) who showed that two thermally stable phases can coexist in pressure equilibrium over a limited range of pressures, close to those observed in the ISM. Since the two-phase model of Field et al. (1969), the thermal and ionization equilibrium of the ISM and its stability have been studied by many authors including different heating and ionizing processes (Black 1987; Kulkarni & Heiles 1988). The response of the ISM to variations in physical processes and parameters are of interest both to a better understanding of the ISM behavior and because of its central role in star formation and galaxy evolution models. Effects on the ISM equilibrium of variations in, for example, X-ray and far UV radiation fields, cosmic ray ionization and metal abundance have been studied by several authors (Shull & Woods 1985; Parravano 1987; Wolfire et al. 1995; Parravano & Pech 1997). In this work, we are interested in a particular process: the flux of ionizing photons coming from the radiative decay of neutrinos (Sciama 1990). Notwithstanding this is a speculative theory, Sciama has argued in a set of papers (Sciama 1993, 1995, 1997a, 1997b, 1998) that it can explain the widespread ionization far from the galactic disk and many other observational results. The simplification in Sciama’s work is to assume a temperature of $\sim 10^4 \text{ K}$ without explicitly solving the thermal equilibrium. The former was made by Dettmar & Schulz (1992) who showed that heat input associated with neutrino decay is too small to account for the observed ISM temperature. However, their conclusion that neutrino decay cannot be a dominant source of ionization could be mistaken, as was pointed out by Sciama (1993), because they neglected the existence of other known heating mechanisms. Our goal here is to analyze, in a more complete and self-consistent way, the effect of ionization due to neutrino decay on the thermochemical equilibrium of the ISM.

In Sect. 2 we discuss the physical processes included in this work and provide the basic equations. Sect. 3 is dedicated to a discussion of the results, and the main conclusions are summarized in Sect. 4.

2. Basic equations

In order to analyze the effect of neutrino decay photons on the thermochemical equilibrium, a simple model for the ISM is used. The included cooling mechanisms are: a) cooling by collisions of electrons with $\text{C}^+$, $\text{Si}^+$, $\text{Fe}^+$, $\text{O}^+$, $\text{S}^+$ and $\text{N}$ ($\Lambda_e$); b) cooling by collisions of neutral hydrogen with $\text{Si}^+$, $\text{Fe}^+$ and $\text{C}^+$ ($\Lambda_H$); and c) cooling due to Ly-α excitation by electrons ($\Lambda_{\text{Ly} \alpha}$). All the cooling rates and the relative abundances were taken from Dalgarno & McCray (1972). We consider the following heating mechanisms:

- a) Interaction of cosmic ray with hydrogen atoms and elec-
trons:
\[ \Gamma_{cr} = \zeta_{cr} \left[ 5 \times 10^{-12}(1 + \Phi)n(1 - \chi) + 5.1 \times 10^{-10}n_{e} \right] \text{ergs cm}^{-3}\text{s}^{-1}, \]  
(1)

where \( n = n(\text{HI}) + n(\text{HII}) \) is the total number density of hydrogen, \( n_{e} \) is the number density of electrons and \( \chi = n(\text{HII})/n \) is the ionization degree of hydrogen. The number of secondary ionizations (\( \Phi \)) was taken from Dalgarno & McCray (1972), and the primary ionization rate is assumed to be \( \zeta_{cr} = 10^{-17} \text{s}^{-1} \) (Spitzer 1978; Black et al. 1995) to estimate the ionization (\( n_{e}/n \)).

b) Heating by \( \text{H}_2 \) formation on dust grains (Spitzer 1978):
\[ \Gamma_{H} = 4.4 \times 10^{-29}n^{2}(1 - \chi) \text{ergs cm}^{-3}\text{s}^{-1}. \]  
(2)

c) Photoelectric heating from small grains and PAHs (Bakes & Tielens 1994):
\[ \Gamma_{pe} = 10^{-24}eG_{\odot}n \text{ ergs cm}^{-3}\text{s}^{-1}, \]  
(3)

where the heating efficiency (\( \epsilon \)) is given by
\[ \epsilon = \frac{4.87 \times 10^{-2}}{[1 + 4 \times 10^{-3}\left(G_{\odot}T^{1/2}/n_{e}\right)^{0.73}]} + \frac{3.65 \times 10^{-2}(T/10^{4})^{0.7}}{[1 + 2 \times 10^{-4}(G_{\odot}T^{1/2}/n_{e})]} \]  
(4)

and \( G_{\odot} \) is the far UV field normalized to its solar neighborhood value.

We only consider ionization/recombination for hydrogen. The recombination rate is given by
\[ X^{-} = \chi n_{e} \alpha(T) \text{s}^{-1}, \]  
(5)

where \( \alpha(T) \) is the recombination coefficient to all states except the ground one, and it was taken from Spitzer (1978). The rate of ionization by cosmic rays is given by
\[ X_{cr}^{-} = \zeta_{cr}(1 + \Phi)(1 - \chi) \text{s}^{-1}. \]  
(6)

We also use the simple analytic fits provided by Wolfire et al. (1995) to estimate the ionization (\( X_{HR}^{-} \)) and heating (\( \Gamma_{HR} \)) due to the soft X-ray background as functions of the column density (\( N_{H} \)) and the electron fraction (\( n_{e}/n \)). In this work we adopt \( N_{H} = 10^{19}\text{cm}^{-2} \).

In addition to the above sources of ionization, we also consider the photons produced by neutrino decay. The ionization due to this mechanism can be written in the form (Sciama 1990):
\[ X_{nu}^{-} = F_{\nu} \sigma(1 - \chi) \text{s}^{-1}, \]  
(7)

where \( \sigma = 6.3 \times 10^{-18} \text{cm}^{2} \) is the absorption cross section of hydrogen and \( F_{\nu} \) is the flux of hydrogen-ionizing photons produced by neutrino decay. In this work \( F_{\nu} \) is a free parameter, although Sciama (1997a) estimated that a value of \( F_{\nu} \simeq 3 \times 10^{4} \text{ photons cm}^{-2}\text{s}^{-1} \) is necessary to produce an electron density \( n_{e} \approx 0.05 \text{ cm}^{-3} \) in the intercloud medium. The most recent (but still uncertain) estimation was \( F_{\nu} \lesssim 10^{5} \text{ photons cm}^{-2}\text{s}^{-1} \) (Sciama 1998).

3. Results and discussion

The thermochemical equilibrium is calculated by solving simultaneously the equations \( \Lambda = \Gamma \) and \( X^{+} = X^{-} \), where \( \Lambda = \Lambda_{e} + \Lambda_{H} + \Lambda_{LY} \) is the total cooling rate, \( \Gamma = \Gamma_{cr} + \Gamma_{H} + \Gamma_{pe} + \Gamma_{HR} \) is the total heating rate, and \( X^{-} = X_{cr}^{-} + X_{HR}^{-} + X_{nu}^{-} \) is the total ionization rate. Fig. 1a shows the equilibrium pressure-density relations for \( G_{\nu} = 1 \) and for three different values of \( F_{\nu} \) (0, 10², and 10⁴ \text{ cm}^{-2}\text{s}^{-1} \). The corresponding electron fractions (\( n_{e}/n \)) are showed in Fig. 1b, where it can be seen that, as expected, \( n_{e}/n \) increases as \( F_{\nu} \) increases. Most of the ionization for the cases \( F_{\nu} > 10^{-2} \text{ cm}^{-2}\text{s}^{-1} \) due to photons coming from neutrino decay, and thus the neutrino decay is a very efficient ionization mechanism. An increase in \( F_{\nu} \) (and the consequent increase in the electron density) enhances the cooling by electron collisions (\( \Lambda_{e} \)). Additionally, the dominant heating mechanism is always photoelectrons from grains and PAHs (\( \Gamma_{pe} \)), which almost is not affected by the flux \( F_{\nu} \). Consequently, for a given density, when \( F_{\nu} \) increases the thermal equilibrium is reached at lower temperatures in the regions where \( \Lambda_{e} \) dominates the cooling (high densities), and the equilibrium curve is shifted down (see Fig. 1a). In contrast, at low densities (\( n \sim 10^{-2} \text{ cm}^{-3} \)), the dominant cooling mechanism is \( \Lambda_{LY} \), which decreases when \( F_{\nu} \) increases and, in this case, the equilibrium is reached at higher temperatures.

Fig. 1a also shows that two regions of thermal stability, i.e., where the slope is positive (Field 1965), always exist and two phases can coexist in pressure equilibrium if the interstellar pressure \( p \equiv p/k \) is between a minimum \( (P_{\text{min}}) \) and a maximum \( (P_{\text{max}}) \) value. For the case \( F_{\nu} = 0 \) we obtain \( P_{\text{max}} \approx 1100 \text{ K cm}^{-3} \) and \( P_{\text{min}} \approx 490 \text{ K cm}^{-3} \); and if we assume an equilibrium pressure of \( P \approx 10^{9} \text{ K cm}^{-3} \), then there can be gas with \( T \approx 8800 \text{ K}, n \approx 0.1 \text{ cm}^{-3} \) and \( n_{e}/n \approx 7 \times 10^{-2} \), and gas with \( T \approx 100 \text{ K}, n \approx 10 \text{ cm}^{-3} \) and \( n_{e}/n \approx 1.7 \times 10^{-3} \) coexisting in equilibrium. These results agree roughly with observational estimations of the warm and cold neutral phases in the local ISM (Kulkarni & Heiles 1988). Furthermore, it can be seen in Fig. 1a that \( P_{\text{max}} \), the maximum pressure value over which only the cold phase can exist, decreases as \( F_{\nu} \) increases. For \( F_{\nu} = 10^{2} \text{ cm}^{-2}\text{s}^{-1} \) and for \( F_{\nu} = 10^{4} \text{ cm}^{-2}\text{s}^{-1} \) we obtain \( P_{\text{max}} \approx 640 \text{ K cm}^{-3} \) and \( P_{\text{max}} \sim 500 \text{ K cm}^{-3} \), respectively; but observations indicate that the pressure in most of the regions of the Galactic plane is \( \gtrsim 10^{3} \text{ K cm}^{-3} \) (Jenkins et al. 1983). Therefore, there seems to be an inconsistency between the observed pressure in a multi-phase medium and high \( F_{\nu} \) values. The basic reason for this behavior (that high \( F_{\nu} \) values imply too low \( P_{\text{max}} \) values) is that neutrino decay is a poor heating agent, while other processes can ionize and heat the ISM. For instance, when the cosmic ray ionization rate (\( \zeta_{cr} \)) is changed (keeping \( F_{\nu} = 0 \) fixed), we find that \( P_{\text{max}} \) decreases as \( \zeta_{cr} \) increases, but for \( \zeta_{cr} \gtrsim 10^{-6} \text{ s}^{-1} \) the heating by cosmic rays (\( \Gamma_{cr} \)) becomes more im-
portant that heating by photoelectrons from grains and PAHs ($\Gamma_{\text{pe}}$), and then $P_{\max}$ begins to increase as $\zeta_{\text{cr}}$ is increased. The minimum $P_{\max}$ value is $\sim 900$ K cm$^{-3}$.

However, more efficient heating mechanisms that those considered here can rise up the equilibrium curve increasing $P_{\max}$. In order to illustrate this effect, we have plotted in Fig. 2 $P_{\max}$ as a function of $F_\nu$ for three different values of $G_0$ (1, 10 and 20) and, in consequence, three different values of $\Gamma_{\text{pe}}$ (believed to be an important heating mechanism in the ISM). We can see that as $F_\nu$ is increased $P_{\max}$ decreases until a minimum value ($\sim 480$ K cm$^{-3}$ for $G_0 = 1$, $\sim 590$ K cm$^{-3}$ for $G_0 = 10$ and $\sim 660$ K cm$^{-3}$ for $G_0 = 20$) and after that remains constant. This occurs when $n_e/n \rightarrow 1$ in the warm gas and, therefore, additional increases in $F_\nu$ do not produce additional changes in this phase. Fig. 2 shows that if an ISM pressure of $\sim 10^{3}$ K cm$^{-3}$ is assumed, a two-phase medium is possible for $G_0 = 1$ only if $F_\nu \leq 10$ cm$^{-2}$ s$^{-1}$, and for $G_0 = 20$ only if $F_\nu \leq 200$ cm$^{-2}$ s$^{-1}$. We conclude that high fluxes of neutrino decay photons ($\gtrsim 10^{3}$ cm$^{-2}$ s$^{-1}$) can be consistent with a two-phase medium only if more efficient heating sources are acting on the gas.

Sciama (1997a) estimated that $F_\nu \sim 3 \times 10^{4}$ cm$^{-2}$ s$^{-1}$ is necessary to produce $n_e \sim 0.05$ cm$^{-3}$ at $T \sim 6000$ K. Fig. 3 shows $n_e$ as function of $F_\nu$ for $T = 6000$ K and for the same three values of $G_0$ given in Fig. 2. The desired electron density at this temperature can be reached at high $F_\nu$ values only if $G_0 \gtrsim 20$ and, again, more efficient heating sources seem to be necessary.

An interesting consequence has to be noted: neutrino beams from neighboring regions may induce the condensation of cold clouds stimulating the formation of stars. The importance of star formation triggered by previously formed stars has been recognized by many authors (see the review of Elmegreen 1992). Triggering mechanisms are usually related to compression of the ISM by shock waves from close supernovas, because the transition warm gas $\rightarrow$ cold gas is promoted if the ISM pressure rises over $P_{\max}$. Although this kind of mechanism can act only over short distances (compared with the Galaxy size) it can propagate over large scales, and the idea of self-propagated star formation has been used to study the formation of spatial patterns in galactic disks (Mueller & Arnett 1976; Gerola & Seiden 1978; Seiden & Gerola 1979; Schulman & Seiden 1990; Jungwiert & Palous 1994). However, the phase transition warm gas $\rightarrow$ cold clouds can be also obtained by decreasing $P_{\max}$ under $P$ (assumed constant) if the local flux of decaying neutrinos increases due, for example, to an increase in the supernova explosion rate. This triggering mechanism depends on the propagation of neutrinos, and therefore can act over large distances in short time intervals. On the other hand, star formation can also inhibit in different ways the warm gas condensation self-regulating the star formation process inclusively over large distances (Cox 1983; Franco & Shore 1984; Struck-Marcell & Scalo 1987; Parravano 1988, 1989). It has been shown that star formation inhibition (rather than stimulation) can also contribute to the formation and maintenance of spatial patterns in galaxies (Freedman & Madore 1984; Chappell & Scalo 1997). Stimulation and inhibition mechanisms of star formation must be acting simultaneously in the Galaxy, but it is not clear yet what spatial scales are important for each one. The effect of non-local star formation stimulation on the formation of spiral patterns in galaxies should be analysed in future models.

4. Conclusions

The thermochemical equilibrium of the ISM, including decay of neutrinos into an ionizing photon flux $F_\nu$, was calculated. The range $0 \leq F_\nu \leq 10^{5}$ cm$^{-2}$ s$^{-1}$ always shows two regions of stability (a warm and a cold phase) that can coexist in equilibrium if the ISM pressure is below a threshold value ($P_{\max}$). High $F_\nu$ values ($\sim 3 \times 10^{4}$ cm$^{-2}$ s$^{-1}$) estimated by Sciama (1997a) to produce $n_e \sim 0.05$ cm$^{-3}$ at $T \sim 6000$ K, only can be consistent with observed ISM pressures if more efficient processes are heating the gas. It also was showed that a neutrino flux increase (due, for example, to an increase in the supernova explosion rate) may stimulate the condensation of cold gas (and probably the star formation) by decreasing $P_{\max}$ under the ISM pressure value.
