We study numerically and analytically the coarsening of stripe phases in two spatial dimensions, and show that transient configurations do not achieve long ranged orientational order but rather evolve into glassy configurations with very slow dynamics. In the absence of thermal fluctuations, defects such as grain boundaries become pinned in an effective periodic potential that is induced by the underlying periodicity of the stripe pattern itself. Pinning arises without quenched disorder from the non-adiabatic coupling between the slowly varying envelope of the order parameter around a defect, and its fast variation over the stripe wavelength. The characteristic size of ordered domains asymptotes to a finite value $R_g \sim \lambda_0 \epsilon^{-1/2} \exp(|a|/\sqrt{\epsilon})$, where $\epsilon \ll 1$ is the dimensionless distance away from threshold, $\lambda_0$ the stripe wavelength, and $a$ a constant of order unity. Random fluctuations allow defect motion to resume until a new characteristic scale is reached, function of the intensity of the fluctuations. We finally discuss the relationship between defect pinning and the coarsening laws obtained in the intermediate time regime.

1. INTRODUCTION

The motion of topological defects in two dimensional smectic phases is studied at a finite distance from threshold. We focus on the Swift-Hohenberg model of Rayleigh-Bénard convection and related amplitude equations to address the role that non-adiabatic effects play in domain coarsening of a modulated phase, defect pinning, and the appearance of glassy behavior.

Topological defects are often the longest lived modes of an equilibrium system, with their motion determining the longest relaxation times of the structure. Phenomenological models of defect motion that are based on a mesoscopic description have been known for some time [12]. Such a description, valid for distances much larger than the defect core, typically involves time dependent Ginzburg-Landau equations or their generalizations. A few cases have been studied extensively, including domain coarsening in O(N) models [20], in nematics [12,13], and in smectic phases as effectively encountered in models of Rayleigh-Bénard convection or lamellar phases of block copolymers [6,13]. In the case of modulated phases, the motion of a single defect has been widely studied within the well known amplitude equation formalism. This method describes the spatio temporal evolution of the envelope of a base periodic or modulated structure [14,15]. The amplitude equation description is valid only close to bifurcation points where the spatial scale of variation of the amplitudes is large or “slow” compared with the “fast” period of the base pattern and, in the present case, with the extent of the defect core as well.

Far enough from the bifurcation threshold of the modulated phase, the separation between slow and fast scales no longer holds, and corrections to the amplitude equations appear because of the coupling between both scales. These corrections are generically referred to as non-adiabatic effects. One manifestation of non-adiabaticity is that a defect that would be expected to move at constant velocity from an amplitude equation analysis may instead remain immobile or pinned [21–23]. We argue below that non-adiabatic effects and defect pinning have important consequences for domain coarsening of modulated phases in two dimensions, and are responsible for the formation of glassy configurations.

Our results complement recent research on glassy properties of stripe phases. It has been suggested that systems in which long ranged order is frustrated by repulsive interactions (the latter often leading to the formation of stripe phases or other patterns in equilibrium) may in fact exhibit the properties of structural glasses. An example are the glassy states recently observed in doped semiconductors in a stripe phase [24]. Coarse grained models with competing interactions of the type used here (and also used to study block copolymer melts in lamellar phases) have been reintroduced to describe the formation of glasses in supercooled liquids [25]. Additional equilibrium studies of the same models in three dimensions based on replica calculations [26] or Monte Carlo simulations [27] have been used to argue for the existence of an equilibrium glass transition. Structural glasses form spontaneously at low temperature without the presence of any quenched disorder, and their properties remain in general poorly understood. It is noteworthy that coarse
grained models exhibiting glassy behavior in the absence of disorder are rare, whereas examples of discrete systems are known (e.g. Ising models with next-nearest neighbor interactions [28,29]). We present here a two dimensional study that indicates a dynamical route to the formation of glassy configurations in stripe phases.

We first analyze the motion of a particular type of defect, namely a grain boundary separating two domains of differently oriented stripes. Earlier asymptotic work near onset (i.e. in the limit $\epsilon \to 0$, where $\epsilon$ is the dimensionless distance away from threshold) is extended to the region of small but finite $\epsilon$. In Section II, grain boundaries are shown to move in an effective periodic potential of wavelength $\lambda_0/2$ (where $\lambda_0$ is the periodicity of the stripe modulation) and of magnitude that increases very quickly with $\epsilon$. Grain boundaries asymptotically pin as the driving force for grain boundary motion decreases. It is argued that for any finite $\epsilon$ an infinite size system will not achieve macroscopic long range order dynamically following a quench. Rather, the characteristic size of a domain will not exceed typical value $R_g$ that is proportional to $\lambda_0 \epsilon^{-1/2} \exp(|a|/\sqrt{\epsilon})$, where $a$ is a constant of order unity.

In Section III, we incorporate the effect of random fluctuations and derive the corresponding amplitude equations valid for fluctuations of small amplitude. The asymptotic motion of a grain boundary can be recast as an escape problem in which the effective activation barrier is seen to be proportional to the grain boundary perimeter.

Our approach must be considered only qualitative in nature because of the scope of the description employed. Ginzburg-Landau equations, and more generally amplitude or order parameter equations (of which the Swift-Hohenberg model described below is but one example) are only asymptotic, large length scale approximations to the physical system they model in the immediate vicinity of a bifurcation point. Therefore any short scale phenomena involved in the description of non-adiabatic corrections clearly falls beyond their range of validity, at least in a systematically quantifiable way. It is nevertheless not unreasonable to expect that non-adiabatic effects of the sort encountered in order parameter equations will also occur in the physical systems which they model. Furthermore, our results also provide insights into many existing numerical studies of these order parameter models, as described below.

In Section IV, we address the consequences of pinning on the domain coarsening that occurs in the intermediate time regime following the quench. This subject has been the focus of several numerical studies [10–15] and, more recently, of experimental studies in block copolymer thin films [30] and in electro-convection in nematics [31]. The results of Sections II and III provide a possible interpretation of conflicting results in the literature. Previous studies of this problem [14,15] addressed the existence of self-similarity during domain coarsening and attempted to quantify the time dependence of the linear scale of the coarsening structure. The statistical self-similarity hypothesis asserts that after a possible transient, consecutive configurations of the coarsening structure are geometrically similar in a statistical sense. As a consequence, any linear scale of the structure (e.g., the average size of a domain or grain of like oriented stripes) is expected to grow as a power law of time $l(t) \sim t^{1/z}$, with $z$ a characteristic exponent. Self-similarity is a well known feature in systems that order in uniform phases of broken symmetry [22,23]. However, the determination of $z$ has been problematic for stripe phases. Its value appears to depend on the quench depth (the value of $\epsilon$), whether or not fluctuations are included in the governing equations, on the thermal history of the system, and on the particular linear scale analyzed.

Recent work in the limit $\epsilon \to 0$ showed that coarsening is self-similar and that $z = 3$ [15]. The value $z = 3$ in that limit can be justified by a dimensional analysis of the law of grain boundary motion. We focus here on the case of finite $\epsilon$ (in practice $\epsilon \geq 0.1$ for the Swift-Hohenberg model), and report a slowing down of phase ordering dynamics with increasing $\epsilon$, in agreement with the literature. We attribute this behavior to partial pinning of defects that becomes increasingly important at long times as the driving force for coarsening decreases. At even longer times, coarsening stops altogether and the system reaches a glassy state as the linear scale of the structure reaches the critical value $R_g(\epsilon$) computed in Section II. When random fluctuations are incorporated in the model, we show that, sufficiently close to onset, the value of $z$ remains independent of the intensity of the fluctuations, thus verifying the universality implied in the self-similarity hypothesis in that region. At larger $\epsilon$, we find that fluctuations accelerate ordering kinetics, also in agreement with the literature, and that, as expected, defect motion is allowed beyond the scale given by $R_g$. At even later times the system orders very slowly, possibly logarithmically in time.

II. NON-ADIABATIC CORRECTIONS AND GRAIN BOUNDARY PINNING

We consider the Swift-Hohenberg model of Rayleigh-Bénard convection [34] as a prototypical model of a modulated phase. The numerical results presented below have been obtained from a direct numerical solution of the model. The analytic results, on the other hand, follow from the corresponding amplitude equation, and hence are expected to be of somewhat wider generality. The model equation studied here is

$$\frac{\partial \psi}{\partial t} = \epsilon \psi - \frac{1}{k_0} \left( k_0^2 + \nabla^2 \right) \psi - \psi^3 ,$$

where $\psi$ is a dimensionless order parameter related to the vertical fluid velocity at the mid plane of a Rayleigh-Bénard convection cell, $\epsilon$ is the reduced Rayleigh number.
\((R - R_c)/R_c \ll 1\) (\(R_c\) is the critical Rayleigh number for instability), and \(k_0 = 2\pi/\lambda_0\) is the roll wavenumber (in Appendix A we outline the connection between this model and other coarse-grained models with long range repulsive interactions \(23\)).

For \(0 < \epsilon \ll 1\), the leading order approximation to the stationary solution of Eq. (1) is a sinusoidal function of wavenumber \(k_0\). We focus in this section on a configuration that contains an isolated grain boundary separating two such stationary solutions with mutually perpendicular wavectors (Figure 3). The reason for studying this perpendicular orientation is the expectation that a 90° grain boundary is that of lowest energy, and hence the prevalent boundary angle in an extended system that evolves spontaneously from an initially disorderd configuration (see, for example, Figure 3,b). It is known that a planar grain boundary separating two regions of uniform \(k_0\) is stationary \(24\), \(20\). However, we found in ref. \(30\) that a slightly perturbed boundary undergoes a net translation with a speed that is a function of the curvature of the rolls ahead of it. We address in this section the extension of the asymptotic results given in that reference to small but finite \(\epsilon\), and show how corrections obtained lead to boundary pinning.

Near threshold, a 90° grain boundary configuration is an approximate solution of Eq. (1) of the form

\[
\psi(x, y, t) = \frac{1}{2} \left[ A(X_A, Y_A, T) e^{i k_0 x} + B(X_B, Y_B, T) e^{i k_0 y} + c.c. \right],
\]

\(2\)

where slow variables are denoted by capital letters and are defined as \(13\), \(20\)

\[
X_A = e^{1/2} x, \quad Y_A = e^{1/4} y;
\]

\[
X_B = e^{1/4} x, \quad Y_B = e^{1/2} y; \quad T = ct.
\]

\(3\)

(The coordinate \(x\) is directed along the normal to the reference planar boundary.)

We recall first some known results for a planar and stationary grain boundary in the limit \(\epsilon \to 0\), a case that was extensively studied in refs. \(13\), \(13\). The stationary amplitudes \(\{A_0, B_0\}\) are a function only of \(x\). \(A_0\), the amplitude of the rolls parallel to the interface, vanishes as \(\exp(x/\sqrt{\epsilon}/\lambda_0)\) when \(x \to -\infty\), and saturates to \((4\epsilon/3)^{1/2}\tanh(x/\sqrt{\epsilon})/\lambda_0\) when \(x \to +\infty\). The behavior of the amplitude of the rolls perpendicular to the interface is slightly different: \(B_0(x) = (4\epsilon/3)^{1/2} \exp(x/\sqrt{\epsilon})/\lambda_0\) when \(x \to -\infty\) and there exists a location \(x^*\) such that \(B_0(x > x^*) \approx 0\) to a good approximation. Hence, the grain boundary region has a thickness proportional to \(\lambda_0/\sqrt{\epsilon}\). It is important to note that at small \(\epsilon\) the location of the grain boundary decouples from the phase of the stripes of domain \(A\). Thus, the configuration obtained is invariant under any translation of the grain boundary by a distance \(x_0\) (the phase of the stripes remaining unchanged).

We next derive two coupled equations for the amplitudes \(A\) and \(B\) that take into account the possible coupling between these amplitudes and the phases of the stripes. This coupling becomes significant at a finite value of \(\epsilon\), and hence when there is a large but finite separation between the scales \(\{X_{AB}, Y_{AB}\}\) and \(\{x, y\}\). We follow an approach similar to that used in ref. \(23\) to study the motion of a planar front between a hexagonal and a uniform phase, or between a hexagonal and a stripe phase. The first step is a multiscale analysis, and is standard \(14\). Equation (1) is expanded in power series of \(\epsilon\), as well as the solution \(\psi = e^{i/2}\psi_{1/2} + e^{i1/2}\psi_{3/2} + \ldots\). The leading order solution \(e^{i/2}\psi_{1/2}\) is given by Eq. (2).

At order \(e^{3/2}\), the solvability conditions for the existence of a nontrivial solution for \(\psi_{3/2}\) yield the relations that \(A\) and \(B\) must satisfy,

\[
\frac{1}{\lambda_0^2} \int_x^{x+\lambda_0} \int_y^{y+\lambda_0} d\psi [L(\psi_{1/2} - \psi_{3/2})^i k_0 x'] = 0 \quad (4)
\]

\[
\frac{1}{\lambda_0^2} \int_x^{x+\lambda_0} \int_y^{y+\lambda_0} d\psi [L(\psi_{1/2} - \psi_{3/1/2}) e^{-ik_0 y'}] = 0 \quad (5)
\]

with the linear operator \(L = 1 - \partial_x k_0^2(\partial^2_{x^2} + \partial^2_{y^2}) + 2\partial_x \partial_y + 2\partial_x \partial_{X_A})^2\). In the limit \(\epsilon \to 0\) the functions \(A\) and \(B\) remain constant over one spatial period \(\lambda_0\), and therefore the only non vanishing contribution to the integrals come from the terms proportional to \(e^{i k_0 x'}\) (resp. \(e^{i k_0 y'}\)) within brackets in Eq. (1) (resp. Eq. (1)). This standard set of coupled Ginzburg-Landau equations follows \(14\), \(14\). It is known, however, that additional non perturbative contributions arising from the term \(\psi_{3/2}'\) appear in Eqs. (4) and (5). We focus next on these contribution and their effect on the relaxation of a slightly perturbed grain boundary.

Integrals of the type \(\int_x^{x+\lambda_0} \int_y^{y+\lambda_0} e^{imk_0 x'} A^n B^p\) in Eqs. (4) and (5) (where \(m, n, p\) are integers) will not integrate to zero if the thickness of the grain boundary profiles along the \(x\) direction is finite. (Contributions from the direction transverse to the grain boundary, \(\int_y^{y+\lambda_0} \int_y^{y+\lambda_0} e^{imk_0 y'} A^n B^p\), will be neglected. They are typically of the order of \(B^2(\partial^2_{y^2})\) and hence always smaller than the leading analytical terms of the amplitude equations.) Terms proportional to \(e^{imk_0 x'}\) will contribute to Eq. (4), and terms proportional to \(e^{imk_0 y'}\) to Eq. (5). If we only retain the lowest order term \(e^{1/2}\psi_{1/2}\) as given by Eq. (1), we find that only \(A^3\) \((m = 3)\) contributes to Eq. (4), while \(3A^2 B\) \((m = 2)\), as well as \(3A^3 B\) \((m = -2)\), with \(A\) the complex conjugate of \(A\), to Eq. (5). Reintroducing the original unscaled variables, the generalized amplitude equations read

\[
\frac{\partial A}{\partial t} = -\frac{\delta F_{gb}}{\delta A} - \frac{1}{4\lambda_0^3} \int_x^{x+\lambda_0} \int_y^{y+\lambda_0} d\psi A^3(x', y', t) e^{2ik_0 x'},
\]

\(6\)
\[
\frac{\partial B}{\partial t} = \frac{\delta F_{gb}}{\delta B} - \frac{3}{4\lambda_0^2} \int_x^{x+\lambda_0} dx' \int_y^{y+\lambda_0} dy' [A^2B e^{i2k_0x'} + A^2B e^{-i2k_0x'}],
\]
where \(F_{gb} = \int d\vec{r} F_{gb}\) is the standard Lyapunov functional corresponding to the 90° grain boundary. Its variational derivatives satisfy [19,20]

\[
\delta F_{gb}/\delta \tilde{A} = \epsilon A + \frac{4}{k_0} \left( \partial_x - \frac{i}{2k_0} \partial_y \right)^2 A - \frac{3}{4} |A|^2 A - \frac{3}{2} |B|^2 A,
\]
and

\[
\delta F_{gb}/\delta \tilde{B} = \epsilon B + \frac{4}{k_0} \left( \partial_y - \frac{i}{2k_0} \partial_x \right)^2 B - \frac{3}{4} |B|^2 B - \frac{3}{2} |A|^2 B.
\]

The last terms in the right hand sides of Eqs. (8) and (9) depend on both fast and slow spatial scales, and they embody the so-called non-adiabatic coupling between the two. Analyzing the effects of these two terms on the relaxation of a perturbed grain boundary is the subject of remainder of this section.

We now introduce a small perturbation to the planar boundary as shown schematically in Figure 1. The phase of the stripes of domain \(A\) is distorted by a uniform perturbation of wavenumber \(q \ll k_0\) (and of amplitude \(\delta x_0 \ll \lambda_0\)) in the direction transverse to the stripes. As shown in ref. [36], approximate solutions to Eqs. (8)-(11) are given by

\[
A = A_0(x - x_{gb}(t)) e^{ik_0 \delta x_0 \cos(qy)},
\]
and

\[
B = B_0(x - x_{gb}(t)),
\]
where \(x_{gb}(t)\) represents the time dependent position of the grain boundary (averaged over \(y\)). As already discussed in that reference, perturbations to the phase of \(B\) are of higher order in \(\epsilon\). In order to derive a law of motion for \(x_{gb}\), it is simpler to neglect the linear relaxation of the perturbed rolls, and hence assume that \(\delta x_0\) is constant. The amplitude \(\delta x_0\) relaxes exponentially with time but the relaxation time of the perturbation is proportional to \(q^{-4}\) and usually much longer than the characteristic time associated with grain boundary motion, \(\lambda_0/\dot{x}_{gb}\). Furthermore, as was shown in ref. [37], explicitly considering stripe relaxation does not change the law of motion for \(x_{gb}\) in any quantitative way.

Multiply Eq. (8) (resp. Eq. (7)) by \(\partial_t \tilde{A}\) (resp. \(\partial_t \tilde{B}\)), add the results and integrate the real part over the system area. By using Eqs. (10)-(11) and integrating by parts the non-adiabatic terms, we obtain the following law of motion for the grain boundary

\[
\dot{x}_{gb} = \frac{\epsilon}{3k_0^2 D(\epsilon)} \kappa^2 - \frac{p(\epsilon)}{D(\epsilon)} \cos(2k_0x_{gb} + \phi),
\]
where \(\kappa = \delta x_0q^2\) is proportional to the mean curvature of the stripes of domain \(A\), \(\phi\) is a constant phase, and

\[
D(\epsilon) = \int_{-\infty}^{\infty} dx \left[ (\partial_x A_0)^2 + (\partial_x B_0)^2 \right],
\]
and

\[
p(\epsilon) = \text{Max}_{\theta} \left\{ \frac{3}{4} \int_{-\infty}^{\infty} dx A_0^4(x) \partial_x A_0(x) \cos(2k_0x + \theta) + \frac{3}{2} \int_{-\infty}^{\infty} dx [2A_0B_0^2 \partial_x A_0 + A_0^2 B_0 \partial_x B_0] \cos(2k_0x + \theta) \right\}.
\]

Equation (12) shows that for any finite \(\epsilon > 0\) a planar grain boundary (\(\kappa = 0\)) can have only two stationary positions per period of the stripe pattern \(\lambda_0\). This effect had been observed numerically and reported in ref. [36], with similar findings also given in ref. [20]. Equation (12) also implies that there exists a critical curvature \(\kappa_g\) below which the grain boundary will remain immobile. This critical curvature is given by

\[
\kappa_g = \frac{1}{R_g} = k_0 \left( \frac{3p(\epsilon)}{\epsilon} \right)^{1/2},
\]
where $R_g$ is the associated radius of curvature which diverges non-analytically near onset

$$R_g \sim \lambda_0 \epsilon^{-1/2} \exp \left( \frac{|\alpha|}{2 \sqrt{\epsilon}} \right). \quad (17)$$

These results have been verified by direct numerical solution of the Swift-Hohenberg model with reasonably small values of $\epsilon$. The numerical algorithm used has been described in Refs. [24,25]. Briefly, Eq. (6) is discretized on a square grid of mesh size $\Delta x = 1$ with $512^2$ nodes ($256^2$ for $\epsilon = 0.5$), and the wavelength is set to $\lambda_0 = 8 \Delta x$. A semi-implicit spectral method is used to iterate in time. The initial condition for $\psi$ is a white and Gaussian random field with zero average and variance $\langle \psi^2 \rangle = \epsilon$. Typical long time configurations which are stationary for all practical purposes are shown in Figs. 2 and 4. These figures show the field $\psi$ in grey scale. Many topological defects including dislocations, $+1/2$ disclinations and several $90^\circ$ grain boundaries can be identified. Figure 2 corresponds to $\epsilon = 0.5$ and two different times $t = 10^4$ and $t = 2 \times 10^4$, showing that the order parameter does not change beyond $t = 10^4$. Figure 4 corresponds to $\epsilon = 0.4$, and the configuration shown remains practically constant beyond $t = 2.3 \times 10^5$.

To further quantify these observations we have computed the probability distribution function of stripe curvatures $P(\kappa, t)$. The stripe curvature is defined as $\kappa = |\nabla \cdot \hat{n}|$, where $\hat{n}$ is the unit normal to the lines of constant $\psi$. The curvature $\kappa$ is a slowly varying quantity away from defect cores, and only these regions are used to compute $P(\kappa, t)$ by the filtering method described in Ref. [24]. Figure 3 shows our results for $\epsilon = 0.4$ and $\epsilon = 0.5$. In both cases the distribution converges at long times towards a limiting curve of finite width, thus indicating that asymptotic configurations contain many curved stripes and are disordered at large scales, or "glassy". This behavior is to be contrasted with that of a coarsening system in which $P(\kappa, t \to \infty)$ would approach a delta function at $\kappa = 0$. We take $P(\kappa = 0, t \to \infty)$ as a measure of the linear scale of the structure or typical domain size and compare its value with the pinning radius $R_g$ given in Eq. (16). Figure 4 shows the numerical results together with $R_g$ multiplied by a (fitted) scale factor approximately equal to 4. The pinning radius $R_g$ increases extremely quickly with decreasing $\epsilon$, in agreement with the numerical calculations for the range of $\epsilon$ which we can study (computational constraints on system sizes have prevented us from investigating the region $\epsilon < 0.30$). We have checked that the glassy configurations at long times do not result from numerical pinning; the results are not modified when the grid spacing is halved to $\Delta x = \lambda_0/16$.

Although other types of defects (e.g., dislocations and $+1/2$ disclinations) may also become pinned, and thus contribute to the overall stability of glassy configurations, the predominance of grain boundaries over other defects seems to be a generic feature of the Swift-Hohenberg model (see Figures 3a, b and ref. [13]). Furthermore it is likely that a similar dependence between the speed of the defect and $\epsilon$ will hold for the motion of other topological defects (except for dislocation climb). Hence we argue that a defected configuration of stripes does not macroscopically order following a quench to a finite value of $\epsilon$.

Asymptotic long time configurations appear to exhibit a labyrinthic and partially disordered structure with many immobile defects that do not anneal away. These disordered configurations resemble those of a structural glass at zero temperature which lack long range order (translational or orientational) order. They become spontaneously trapped in metastable configurations that are very different from the configuration of lowest free energy (all stripes parallel to each other, or a "crystalline" state).

Not all grain boundaries in a glassy configuration are $90^\circ$ boundaries. However, we expect that grain boundaries with a different orientation would be pinned less efficiently (i.e., would have a higher value of $|\alpha|$ in Eq. (16)). The reason is that their stationary planar profile is smoother than that of a $90^\circ$ grain boundary, and therefore non-adiabatic effects are expected to be weaker.

We finally mention that if both $\epsilon$ and $\kappa \lambda_0$ are not small compared to one, both adiabatic and non-adiabatic terms will contain higher order analytic corrections which we have not calculated.

### III. Motion at Finite Temperature

Given the results of Section II, it is natural to study the effect of random fluctuations added to Eq. (6). Small amplitude fluctuations will allow activated motion of grain boundaries, and in general unpinning. We consider in this section the stochastic Swift-Hohenberg model

$$\frac{\partial \hat{\psi}}{\partial t} = \epsilon \hat{\psi} - \frac{1}{k_0^2} (k_0^2 + \nabla^2)^2 \hat{\psi} - \hat{\psi}^3 + \eta(\vec{r}, t) , \quad (18)$$

where $\eta$ is a Gaussian and white random noise of zero mean and variance

$$\langle \eta(\vec{r}, t) \eta(\vec{r}', t') \rangle = 2F \delta(\vec{r} - \vec{r}') \delta(t - t') . \quad (19)$$

The noise intensity $F$ is proportional to the (dimensionless) temperature according to the fluctuation-dissipation theorem. In what follows, $F$ and $\epsilon$ are considered as independent parameters, although they might be related in some particular physical systems. The stochastic Swift-Hohenberg model has been used to study hydrodynamic fluctuations near onset of Rayleigh-Bénard convection [37], and thermal fluctuations of molecular origin in lamellar phases of diblock copolymers [38].

The stationary states of Eq. (18) in two spatial dimensions have been studied in Refs. [39,11]. Above a critical noise intensity $F_c$ (that depends on $\epsilon$), the system is disordered (lacks both translational and orientational long ranged order). Below $F_c$ a stripe phase with long
ranged orientational order but no translational order was found. Only at \( F = 0 \) the system was seen to exhibit both translational and orientation long ranged order. In what follows we focus on defect dynamics in the range \( 0 < F \ll F_c \), so that the local stripe pattern is not very distorted.

We first derive the stochastic amplitude equations for a 90° grain boundary. Following Graham [11], we approximate the effect of the noise on the amplitudes by projecting it along the two slow modes of the deterministic equation and neglecting any contribution arising from couplings and resonances between noise and fast variables [11]. We start by writing the random function as,

\[
\eta(x, t) = \frac{1}{2} \left[ e^{ik_0x} \tilde{a}(X_A, Y_A, T) + e^{-ik_0y} \tilde{b}(X_B, Y_B, T) + \text{c.c.} \right],
\]

where the slow variables \( X(Y)_{A,B} \) are given by Eq. (3), and \( \tilde{a} \) and \( \tilde{b} \) are two independent complex random processes that satisfy the relations,

\[
\langle \tilde{a} \rangle = 0, \quad (\tilde{a} \tilde{b}^*) = 0,
\]

It is implicit in the decomposition that \( \tilde{a} \) and \( \tilde{b} \) are two independent complex random processes that satisfy the relations,

\[
\langle \tilde{a} \rangle = 0, \quad \langle \tilde{a} \tilde{b}^* \rangle = 0,
\]

\[
\langle \tilde{a} \tilde{b}^* \rangle = 2F\delta(\tilde{x} - \tilde{x}')\delta(t - t').
\]

We can now estimate the escape rate of a grain boundary via

\[
\dot{x}_{gb} = \frac{e}{3k_0^2 D(e)} \kappa^2 - \frac{p(e)}{D(e)} \cos(2k_0x_{gb} + \phi) + \tilde{\eta},
\]

with \( \tilde{\eta} \) a (real) random white Gaussian noise satisfying,

\[
\langle \tilde{\eta} \rangle = 0, \quad \langle \tilde{\eta}(t) \tilde{\eta}(t') \rangle = 2F' \delta(t - t'), \quad F' = F/|2D(e)\kappa_0|.
\]

Equations (23) and (24) can be recast as

\[
\dot{x}_{gb} = \left( \frac{k_0 F_0}{2D} \right) R_g \kappa^2 - \left( \frac{k_0 F_0}{2D} \right) \frac{1}{R_g} \cos(2k_0x_{gb} + \phi) + \frac{1}{\sqrt{2D}} \left( \frac{F}{R_g} \right)^{1/2} \xi.
\]

The random term \( \xi \) is such that \( \langle \xi \rangle = 0 \) and \( \langle \xi(t) \xi(t') \rangle = 2\delta(t - t') \). We have also used Eq. (10) to eliminate \( p(e) \) from Eq. (23), and we have defined

\[
F_0 = \frac{2e}{3k_0^2 R_g}.
\]

Consider the situation where grain boundaries are pinned at \( F = 0 \). Since \( \kappa < \kappa_g \), the first term of the right-hand-side of Eq. (23) is not dominant and the potential barrier that a pinned defect of size \( R_g \) has to overcome is of the order of \( F_0/R_g \). The stochastic problem is now an escape problem over this potential barrier given the intensity of the noise term in Eq. (23). The Kramers rate of escape is given by

\[
r \sim \exp \left( -\frac{F_0}{F} \frac{R_g}{R_g} \right).
\]

Therefore a noise intensity

\[
F = R_g \frac{F_0}{R_g} \sim R_g k_0^{-1} \epsilon^2 e^{-|\alpha|/\sqrt{\tau}}
\]

is required to un-pin a grain boundary of length \( R_g \).

**IV. SLOW COARSENING DYNAMICS: DEPENDENCE ON TEMPERATURE AND QUENCH DEPTH.**

We use here the results of Sections [11] and [11] to provide a possible interpretation of conflicting results concerning domain coarsening of stripe phases. We recently studied this issue by numerically solving the noiseless Swift-Hohenberg equation (Eq. (1)) in the limit \( \epsilon \to 0 \).
Our numerical results suggested that the characteristic scale of the structure (or the typical size of ordered domains) increases as $t^{1/2}$, with $z = 3$. That value of the exponent was interpreted to follow from the dominant motion of grain boundaries through a background of curved stripes. In disordered configurations, the curvature of stripes is set by a distribution of largely immobile $+1/2$ disclinations. According to Eq. (23), the motion of grain boundaries is driven by stripe curvature, and acts to reduce the overall curvature by replacing regions of curved stripes by straight ones of a different orientation. It also reduces the disclination density whenever their core region is swept by a moving grain boundary. In the limit $\epsilon \ll 1$ we computed several measures of the linear scale, including moments of $P(\kappa, t)$, moments of the structure factor of the order parameter, and the average distance between defects. They were all found to become proportional to each other, and to grow as a power law of time with an exponent $1/3$.

Grain boundary motion as described in Section I was used to provide an interpretation for the value $z = 3$. Since $+1/2$ disclinations generate roughly axisymmetric patterns of stripes around them, the characteristic stripe curvature in any given configuration is proportional to the inverse characteristic distance between disclinations. Under the self-similarity hypothesis, the distance between disclinations is proportional to $l(t)$, hence $\kappa \sim 1/l(t)$. If grain boundaries are the class of defect the motion of which controls asymptotic coarsening, then the coarsening exponent can be inferred by dimensional analysis of Eq. (12). In the limit $\epsilon \rightarrow 0$, the oscillatory term in the right hand side of Eq. (12) can be neglected and we simply have $dl/dt \propto l^{-2}$ or $l(t) \sim t^{1/3}$, in agreement with the numerical solution of Eq. (11).

Equation (12) shows that this result changes qualitatively further from onset. As $\epsilon$ increases the pinning potential energy barrier $\rho(\epsilon)$ increases extremely fast, and important corrections to scaling are to be expected. For finite $\epsilon$ and short times many defects are present, therefore the characteristic curvature of the stripes is very large, and the first term in the right hand side of Eq. (12) dominates. As coarsening proceeds, the characteristic curvature decreases until it reaches the critical value $\kappa_g$ given by Eq. (10). At that point the typical velocity of a grain boundary vanishes, although the system is still disordered. Therefore one would expect that coarsening would stop when $l(t)$ is of the order of $R_g$. This is precisely the results shown in Fig. 2 with only one adjustable parameter (a scale factor relating $R_g$ given by Eq. (14) to $l(t)$ determined numerically from the distribution of stripe curvatures).

When random fluctuations are considered ($F > 0$ in Eqs. (15)-(19)), some of the grain boundaries in a frozen configuration are expected to resume motion. We argue that the structure will continue coarsening until the average domain size reaches a new characteristic size $l_F > R_g$ that can be estimated as follows. We write a general phenomenological evolution equation for the domain size $l(t)$ directly from Eq. (23):

$$\frac{dl}{dt} = \left(\frac{k_0F_0}{2D}\right) R_g - \left(\frac{k_0F_0}{2D}\right) \frac{1}{R_g} \cos(2k_0l + \phi)$$

$$+ \frac{1}{2\sqrt{D}} \left(\frac{F}{t}\right)^{1/2} \xi,$$

(29)

where we have assumed that, prior to pinning, the various length scales remain approximately proportional to each other. Recall from Eq. (27) that $F = F_0$ is required to unpin a configuration obtained in the absence of noise, for which $l(t) \sim R_g$. According to Eq. (29), coarsening proceeds if $F > F_0$ until a new characteristic pinning size is reached given by $F_0 l_F/(F R_g) = 1$ or

$$l_F = R_g \frac{F}{F_0} \sim k_0 F \frac{e|\alpha|/\sqrt{\xi}}{\epsilon^2}.$$

(30)

After reaching the scale $l_F$, domains are expected to coarsen very slowly by thermal activation. When a grain boundary overcomes one pinning barrier, the linear extent of the corresponding domain typically increases by an amount of order $\lambda_0 / 2$. Hence $dl/dt \sim \lambda_0 r$, where $r$ is given by Eq. (27) with $R_g$, replaced by $l$. Hence domains are expected to grow logarithmically in time according to

$$l(t) \sim F \ln(t/F) \quad \text{for } l \gg l_F.$$  

(31)

A numerical solution of Eq. (18) yields results qualitatively consistent with those presented above. Figure 6 shows a configuration of the order parameter field $\psi$ obtained for $F = 0$ and $\epsilon = 0.4$ starting from random initial conditions. The configuration shown corresponds to very late times $t = 2.3 \times 10^5$ at which point all defects are practically immobile, and domain growth has stopped. Then we set $F = 0.00318$, and the integration is continued. The order parameter configuration $t = 10^5$ time units later is shown in Fig. 6b. The average domain size has increased substantially. Many grain boundaries have a 90° orientation (like in Fig. 6a), and roughening is limited or nonexistent. We have determined the average domain size $l$ from the probability distribution function of the quantity $\zeta = \psi^2 + (\nabla \psi)^2/k_0^2$. Figure 6b shows the probability distribution function corresponding to a perfectly ordered configuration, as well as to partially disordered configurations. The inverse linear scale $1/l$, proportional to the defect density $\rho_d$, is extracted from the difference between these curves, as detailed in Appendix 2. As shown in Fig. 6, domain growth is very slow, possibly logarithmic, although a precise check of this behavior is problematic.

Figure 6 displays the evolution of the defect density $\rho_d(t)$ as a function of time, starting from random initial configurations. For reference we also show the case $F = 0$. Increasing the value of $\epsilon$ leads to smaller effective exponents, whereas increasing $F$ has the opposite effect. For sufficiently small $\epsilon$, we find $z = 3$ independent of the value of $F$. The two bottom curves correspond to
systems that are close enough to onset, and hence either $R_q$ or $l_F$ is very large compared with the linear size of the system. We show our results for $\epsilon = 0.04$ (averaged over 40 independent runs) and for $\epsilon = 0.15$ (averaged over 15 independent runs). The solid line closest to these two curves has a slope of $-1/3$. The downward deviation from linearity at long times at $\epsilon = 0.04$ is a typical manifestation of finite size effects (this long time behavior and its dependence on the system size was studied in detail in ref. [15]).

With increasing $\epsilon$ and/or decreasing $F$, pinning becomes more pronounced as evidenced the lower effective slopes of the three upper curves in Fig. 8 (the results are averages over six independent runs, each curve corresponding to the same value $\epsilon = 0.4$). The top curve corresponds to a system without fluctuations for which $\rho_d$ was computed with the method described in ref. [15]. The density starts decaying roughly as an inverse power law, $\rho_d \sim 1/\ln(t)$. The curve below, denoted by plus signs, corresponds to a noise intensity three times larger than the previous case. Its initial decay is slightly faster (it can be fitted with an effective exponent $1/z_{eff} \approx -2.23$ as shown with the solid line in the figure), and the up-wards deviations at long times are less pronounced. This behavior is in qualitative agreement with the the expectation that defects overcome pinning barriers more readily at higher noise intensities and pinning is postponed to longer times when $l \sim l_F$. However, the effective initial decay is slower than $t^{-1/3}$ which we interpret as a crossover effect resulting from non-adiabaticity.

In summary, our results for large $\epsilon$ are in agreement with earlier numerical results performed at $\epsilon = 0.25$, showing that coarsening laws are very slow and depend on the presence of thermal fluctuations. We argue here that a coarsening exponent can be properly determined only in the small $\epsilon$ limit, where the phase ordering kinetics is self-similar. Our results support that the exponent $z = 3$ is independent of $F$ for sufficiently small $\epsilon$, when pinning effects are negligible ($R_q$ much larger than the linear size of the system).

V. CONCLUSIONS

We have shown that the Swift-Hohenberg model of Rayleigh-Bénard convection exhibits glassy properties in spatially extended systems. In the absence of fluctuations, and following a parameter quench across threshold, random initial configurations do not evolve into completely ordered states, a single plane-wave or crystalline state. Instead, they reach disordered metastable configurations in which topological defects, mainly grain boundaries and disclinations, fail to annihilate and remain with finite density. It appears that the formation of these glassy configurations in a quenched disorder-free system can be accounted for by the finite separation between “fast” length scales of the structure (associated with stripe periodicity), and “slow” scales (associated with the extent of defect envelopes). Since at a finite distance from threshold the ratio between these two scales is finite, non-adiabatic effects lead systematically to defect pinning in an infinite system. Fluctuations allow unpinning and a certain amount of “crystallization”, albeit through an asymptotically slow activated motion of grain boundaries and other defects.

The present framework is far too simple to be used in the prediction of a glass transition temperature, if such a transition exists. In some respects, the situation just described is instead very similar to that of domain growth in random fields in dimension larger than two [14,15]. There, domain walls separating magnetized domains are pinned by fixed impurities and evolve by thermal activation to other more favorable configurations. The phenomenological pinning energy of a domain of size $R$ grows as $\Upsilon R^d$, were $\Upsilon$ depends on the problem considered, yielding an escape rate given by $r \sim \exp(-\Upsilon R^d/k_B T)$, equation that is formally analogous to Eq. (27) with $\theta = 1$. Two crucial differences are that our system is glassy even in two dimensions, and that defects do not need any disorder to become pinned.

The consequences of defect pinning on the intermediate time regime corresponding to domain coarsening have also been investigated. A universal coarsening exponent can be determined close to threshold only, where we obtain $z = 3$. Coarsening stops when the linear size of the system is larger than the characteristic domain size for pinning. In this situation, an intermediate crossover regime is anticipated with lower effective coarsening exponents, as is observed in numerical solutions of the model. Crossover effects induced by pinning can be reduced by either increasing the intensity of the fluctuations or approaching threshold.

We note that some of our conclusions as well as our interpretation of the numerical results are based on the analysis of a particular type of defect, namely a grain boundary separating two domains with differently oriented stripes. We think it is likely that similar non-adiabatic corrections to defect motion will appear for dislocation glide or disclination motion, leading to similar non perturbative corrections in $\epsilon$ to the speed of the defect.

We believe more generally that pinning through non-adiabatic effects is likely to be a feature of a wide variety of pattern forming systems, and is not limited to the particular model treated here. Block copolymer melts, for instance, provide an interesting case in which the results obtained could have practical implications (see Appendix A for a summary of the relevant equations and their re-
relationship with the model studied here). We also mention here that results qualitatively similar to ours have been reported for a model with competing interactions (describing ferromagnetic films), that is defined by the equations of Appendix A with a different form of the Green’s function $G$. There, frozen polycrystalline configurations of stripe patterns were observed for deep quenches as well, whereas the system could reach an ordered state for shallower quenches. This same model was also able to predict the formation of a frozen phase composed of polydisperse droplets with a near-hexagonal arrangement, as previously observed in experiments on a Langmuir monolayer. However, the pinning mechanism involved in this last case is probably different than the one discussed in the present paper since the patterns are no longer locally periodic. Nevertheless, we would expect that our main conclusions can be readily extended to other systems with periodic structures such as hexagonal patterns.

**APPENDIX A: MEAN-FIELD MODEL OF A SYMMETRIC BLOCK COPOLYMER MELT**

We briefly recall in this appendix known results about the relationship between the mean field description of a block copolymer melt, and the amplitude equation for Swift-Hohenberg model (Eq. (1)) at first order in $\epsilon$. The dynamics of micro-phase separation of block copolymers is often modeled by a time-dependent Ginzburg-Landau equation for a conserved order parameter $\psi$,

$$\frac{1}{M} \frac{\partial \psi}{\partial t} = \nabla^2 \left[ - (2 + \epsilon)\psi + \psi^3 - \frac{1}{k_0^2} \nabla^2 \psi \right] - k_0^2 (\psi - \psi_\infty),$$

(A3)

where $\psi_\infty$ is the boundary condition at infinity. In most studies, it is customary to set $\psi_\infty = (\psi)$, the spatial average of $\psi$ over the sample. We introduce the amplitude $A$ of slightly modulated waves through,

$$\psi(\mathbf{r},t) = \frac{1}{2} [A(\mathbf{r},t) \, e^{i k_0 x} + \text{c.c.}],$$

(A4)

A multi-scale analysis of Eq. (A3) in the limit $\epsilon \ll 1$ was conducted by Shiwa. Setting $M = 1/k_0^2$, the resulting equation for the amplitude is

$$\frac{\partial A}{\partial t} = \epsilon A + \frac{4}{k_0^2} \left( \partial_x - \frac{i}{k_0^2} \partial_y \right)^2 A - \frac{3}{4} |A|^2 A,$$

(A5)

which is identical to the amplitude equation of the Swift-Hohenberg model. Note that the only effect of the conservation law on the local part of the free energy (the Laplacian operator in front of the square bracket in Eq. (A3)) is a renormalization of the mobility $M$. The quantities $\epsilon$ and $k_0$ defined above play the same role as the same coefficients in the Swift-Hohenberg model (i.e. the dimensionless distance to threshold and the dominant wavenumber of the structure, respectively.)

**APPENDIX B: CALCULATION OF THE DEFECT DENSITY IN THE PRESENCE OF FLUCTUATIONS**

Computation of the domain size from the probability distribution of stripe curvature is delicate in the presence of noise. We have used a different method than that used for $F = 0$. We introduce an effective squared amplitude $\zeta(\mathbf{r},t)$ by

$$\zeta = \psi^2 + (\nabla \psi)^2 / k_0^2.$$  

(B1)

For a perfectly ordered system consisting of a plane-wave solution of the Swift-Hohenberg equation and $F = 0$, the probability distribution function of $\zeta$ is a delta function at $\zeta_\infty = 4\epsilon/3$. When $F > 0$ the probability distribution function of $\zeta$ even for a plane wave $p^{(F)}(\zeta)$ is broader because of “phonon” excitations. The function $p^{(F)}(\zeta)$ is plotted in Figure 3 (with dotted lines), and is then used as a reference curve for a fixed $F$. In a partially disordered configuration, the presence of defects and curved stripes further broadens the probability distribution function to $p^{(F)}(\zeta, t)$ (solid lines of Figure 3). The difference between the two curves is related to the degree or disorder beyond small fluctuations away from a perfectly ordered structure. We define the defect density by $\rho_d(t) = \max\{p^{(F)}(\zeta_\infty), \zeta\} - \max\{p^{(F)}(\zeta, t), \zeta\}$. 

\[ \rho_d(t) = \max\{p^{(F)}(\zeta_\infty), \zeta\} - \max\{p^{(F)}(\zeta, t), \zeta\}. \]
Since grain boundaries are seen to be the major contribution to defect density, one can introduce a characteristic length scale $\rho_d^{-1}$, which is further identified with the characteristic size, or domain size $l$. In Figure 3, $l$ has been normalized so that $l(t = 0) = R_p$ (at the beginning of the heating process) where $R_p$ is computed from the probability distribution function of stripe curvatures at $F = 0$.

FIG. 1. Schematic grain boundary configuration separating two domains of stripes $A$ and $B$ of the same periodicity ($|\vec{k}_0| = |\vec{k}_0'| = k_0$). The stripes of domain $A$ are weakly curved by a transverse modulation of wavenumber $q \ll k_0$. $\delta x_0$ represents the magnitude of the phase modulation.

FIG. 2. Glassy configurations obtained by numerical solution of the Swift-Hohenberg model with random initial conditions. Dimensionless times shown are (a), $t = 10000$; and (b), $t = 20000$. Here $\epsilon = 0.5$ and the system has $256^2$ grid nodes.
FIG. 3. Probability distribution function of stripe curvatures, $P(\kappa, t)$, after a quench at $\epsilon = 0.5$ (dotted lines) and $\epsilon = 0.4$ (solid lines), averaged over 10 and 6 independent runs respectively. For $\epsilon = 0.5$ the figure shows the curves obtained at times $t = 10^4$, $5 \times 10^5$ and $10^5$, and for $\epsilon = 0.4$ at times $t = 6 \times 10^4$, $1.2 \times 10^5$ and $2.3 \times 10^5$. 
FIG. 4. Characteristic asymptotic grain size following a quench as a function of $\epsilon$. (a), estimate given by Eq. (16). (b), numerical value of $P(\kappa = 0, t = \infty)$ (symbols) compared also with Eq.(16) multiplied by one fitted scale factor (solid line).
FIG. 5. (a) Near stationary configuration obtained after a quench at $\epsilon = 0.4$ and in the absence of fluctuations $F = 0$ (the time shown is $t = 2.3 \times 10^5$, and the system size includes $512^2$ nodes). (b) New structure obtained after taking the configuration shown in (a) as an initial condition and further integrating the model equations with $F = 0.00318$ for a period of $10^5$ time units. At this time, any boundary motion is very slow.
FIG. 6. Probability distribution function of $\zeta$ defined by Eq. (B1) with $\psi$ the solution of Eq. (18), for $F = 0.00636$ and $\epsilon = 0.4$. The dotted line corresponds to a single plane wave with superimposed fluctuations, while the solid line correspond to disordered configurations obtained from random initial conditions (at times $t = 5 \times 10^3$, $10^4$ and $10^5$, respectively).
FIG. 7. Characteristic domain size as a function of time at $\epsilon = 0.4$ and $F \neq 0$ as indicated in the figure. The initial condition at time $t = 0$ is a glassy configuration obtained from a previous run with $F = 0$. 
FIG. 8. Defect density in arbitrary units as a function of time for several values of $\epsilon$ and $F$. The straight solid lines are guides to the eye with slopes, from bottom to top, $-0.33$, $-0.33$, $-0.23$ and $-0.20$.
