Abstract. We present the X-ray spectrum of TW Hya observed at high and intermediate spectral resolution with the Reflection Grating Spectrometer (RGS) and the European Photon Imaging Camera (EPIC) onboard the \textit{XMM-Newton} satellite. TW Hya is the first classical T Tauri star for which simultaneous X-ray data with both high spectral resolution and high sensitivity were obtained, thus allowing to probe the X-ray emission properties of stars in the early pre-main sequence phase. Despite TW Hya's high X-ray luminosity in excess of $10^{30}$ erg/s its X-ray spectrum is dominated by emission lines from rather cool plasma (T $\approx$ 3 MK), and only little emission measure is present at high temperatures (T $\approx$ 10 MK). We determine photon fluxes for the emission lines in the high resolution spectrum, confirming the earlier result from \textit{Chandra} that the predominant emission is from neon and oxygen, with comparatively weak iron lines. Further, the line ratios of He-like triplets of nitrogen, oxygen and neon require densities of $n_e \sim 10^{13}$ cm$^{-3}$, about two orders of magnitude higher than for any other star observed so far at high spectral resolution. Finally, we find that nearly all metals are underabundant with respect to solar abundances, while the abundances of nitrogen and neon are enhanced. The high plasma density, the (comparatively) low temperature, and peculiar chemical abundances in the X-ray emitting region on TW Hya are untypical for stellar coronae. An alternative X-ray production mechanism is therefore called for and a natural explanation is an accretion column depleted of grain forming elements. The metal depletion could be either due to the original molecular cloud that formed TW Hya or due to a settling of dust in the circumstellar disk of TW Hya.

Key words. X-rays: stars – stars: individual: TW Hya – stars: pre-main sequence, coronae, activity – accretion

1. Introduction

T Tauri stars (TTS) are late-type pre-main sequence (PMS) stars, usually found in or near star formation regions. The two subclasses of TTS, termed 'classical' and 'weak-line', are distinguished by the strength of their H$_\alpha$ emission. This empirical distinction most likely also reflects different evolutionary states: Most of the 'classical' TTS (cTTS), i.e., those with strong H$_\alpha$ emission, show signatures of circumstellar matter (e.g. IR and UV excesses) accreting onto the central star, while in contrast, 'weak-line' TTS (wTTS) show no signs for the presence of disks which presumably have been lost. A detailed description of early stellar evolution and the observable stellar properties related with the different phases can be found in \cite{Feigelson1999}.

X-ray emission from TTS was first detected with the \textit{Einstein} satellite (e.g. \cite{Feigelson1981, Walter1981, Montmerle1983}). It was soon recognized that X-ray observations provide an efficient means of discovering wTTS which can easily escape other identification methods because of their lack of conspicuous features in the optical or near-infrared. Extensive X-ray studies of a variety of star forming regions were undertaken with \textit{ROSAT}. In particular the spatial completeness of the \textit{ROSAT} All-Sky Survey has resulted in a large number of newly identified PMS stars (e.g. \cite{Neuhaeuser1995, Alcala1995, Wichmann1996}).

The origin of the X-ray emission from wTTS is commonly interpreted in terms of scaled-up solar-type magnetic activity, but the situation is less clear for their accreting counterparts, the cTTS. While nothing should prevent the formation of magnetic fields and ensuing coronae in cTTS, X-rays could alternatively also be produced above the hot spot where a magnetically funnelled accretion flow impacts on the surface of the star (\cite{Lamzin1999}). A distinction between a corona or an accretion funnel as the site of X-ray emission in cTTS requires a precise assessment of the physical conditions in the X-ray emitting region. With the lower resolution X-ray data available from \textit{Einstein}- and \textit{ROSAT}-observations of both cTTS and wTTS it was impossible to adequately characterize the emission site, al-
though some differences between the two types of TTS were indicated by statistical comparisons of their emission level and variability (see e.g. Neuhäuser et al. 1995; Stelzer et al. 2000; Stelzer & Neuhäuser 2001a).

With the advent of high-resolution X-ray spectroscopy with the grating spectrometers onboard the XMM-Newton and Chandra observatories this situation has fundamentally changed. The reflection gratings onboard XMM-Newton and the transmission gratings onboard Chandra have spectral resolutions sufficiently large to resolve individual emission lines in the soft X-ray range. These emission lines and in particular the analysis of their relative strengths provide unprecedented tools for the plasma diagnostics of the outer envelopes of stars and allow an assessment of the temperature structure, density, and chemical abundances in the X-ray emitting region.

The high signal-to-noise ratio (SNR) required for a meaningful analysis of high-resolution X-ray spectra clearly favors the study of the nearest star forming regions. The nearby TTS TW Hya (located at a distance of only $\sim 57$ pc; Wichmann et al. 1998) was first thought to be an isolated cTTS (Rucinski & Krautter 1983), but later five more stars were found in the same region and shown to be members of a physical cluster of young stars dominated by TW Hya. The whole group is now known as the TW Hydra association (TWA; Kastner et al. 1997), which is currently known to host about 20 young stars (youth being probed by Li absorption), most of which – in contrast to TW Hya itself – are wTTS.

The first – and so far only – example of a high-resolution X-ray spectrum of an accreting PMS star was a Chandra/HETGS spectrum of TW Hya presented by Kastner et al. (2002). Interestingly, flux ratios of the OVII triplet lines indicated densities much higher than found in any stellar corona before, and consequently Kastner et al. (2002) called into question the solar-stellar analogy for TW Hya and cTTS in general. About a year after the Chandra observation TW Hya was observed by XMM-Newton, resulting in a higher SNR grating spectrum with the XMM-Newton Reflection Grating Spectrometer (RGS) as well as a simultaneously measured medium-resolution CCD spectrum with high sensitivity over a broad energy range ($E = 0.3 - 10$ keV) from the European Photon Imaging Camera (EPIC). The purpose of this paper is to present the results of this 30 ksec XMM-Newton observation and properly discuss their implications in the context of X-ray emission from TTS.

### 2. Observations

TW Hya was observed with XMM-Newton on July 9, 2001 for a duration of 30 ksec (obs-id 0112880201) with the RGS as prime instrument. The observations were performed in full-frame mode employing the medium filter for both the MOS and pn cameras of EPIC. Because of the optical brightness of TW Hya ($V = 11$ mag) the Optical Monitor (OM) was in blocked position so that no concurrent optical data is available. The observing log for all X-ray instruments onboard XMM-Newton is given in Table 1.

TW Hya is by far the brightest X-ray source and the only known member of the TW Hya association in this EPIC field. By inspecting the time-resolved background emission we verified that the background was low and showed only little time variability without any significant solar-activity related contamination, so that the full observing time provided data useful for analysis. The pn data shows slight evidence for pile-up. Therefore, we base our analysis on the MOS detectors, which furthermore provide a better energy resolution.

We constructed an X-ray light curve of TW Hya by binning all photons from a circular area around the target position. We used an extraction radius of 40" including about 90% of the source photons. For the background subtraction we used a source-free circle of the same area located near TW Hya. Background subtracted MOS lightcurves of TW Hya in the energy range $0.3-2$ keV are shown in Fig. 1. The counts collected by MOS 1 and MOS 2 have been added to increase the SNR.

To investigate spectral changes during the observation we defined two energy bands, $S$ for “soft” and $H$ for “hard”, and computed a hardness ratio $HR = (H - S)/(H + S)$. The overall X-ray spectrum of TW Hya is very soft, with only a few photons recorded above $\sim 2$ keV (see discussion below). To ensure sufficient signal in both bands we chose $S = 0.3 - 1.0$ keV and $H = 1.0 - 2$ keV. The time evolution of $HR$ is shown in the lower panel of Fig. 1. Neither the lightcurve nor the evolution of the $HR$ show conspicuous signs for flaring.

### 3. High-resolution Spectrum: RGS

The RGS data of TW Hya were analysed using the standard pipeline rgsproc of the XMM-Newton Science Analysis System (SAS), version 5.4.1. We extracted the total (source plus background) and a background spectrum for TW Hya. In this paper only the first dispersion order is discussed. The full first order RGS spectrum of TW Hya is displayed in Fig. 2 except for the small range between $35 - 37$ Å where no spectral lines were found. In Fig. 2 identifications of the stronger emission lines are also provided from comparisons with line lists of the MEKAL code (Mewe et al. 1985; Mewe et al. 1995), the National Institute of Standards (NIST) data base, and the results of solar flare observations (Phillips et al. 1999). In the RGS spectrum one recognizes the lines of H-like and He-like carbon, nitrogen, oxygen and neon, while iron lines are weak or absent (especially those near 15 and 17 Å). The typical silicon and magnesium lines below 10 Å are also absent in the RGS spectrum. Note, however, that at those wavelengths the RGS effective area decreases rapidly.

### Table 1. Observing log for the XMM-Newton observation of TW Hya on July 9, 2001.

| Instr. | UT [hh:mm:ss] | JD - 2452099 | Expo [ksec] |
|--------|--------------|--------------|-------------|
| pn     | 06:35:38     | 13:57:31     | 0.774306    | 1.081250    | 26.52 |
| MOS    | 05:58:02     | 14:01:48     | 0.748611    | 1.084028    | 28.98 |
| RGS    | 05:51:39     | 14:05:15     | 0.743750    | 1.086806    | 29.64 |
shown that a Lorentzian profile provides a reasonable description of the shape of RGS line profiles (e.g. Ness et al. 2002, Stelzer et al. 2002). Before feeding the spectra into CORA we corrected for the different extraction area of total and background variations we selected successive wavelength intervals in which the background can be approximated by a constant level. To account for uncertainties associated with the background level we add a systematic error to the statistical error of the line counts. This systematic error was derived by using the highest and lowest background levels that provide an acceptable line fit after visual inspection of the solution. Finally, the line counts and their errors (both statistical and systematic) were transformed into photon fluxes with the help of the effective areas of the RGS.

A list of the brightest lines in the spectral range of the RGS (6 − 37 Å) is provided in Table 2, where we list the lines’ central wavelengths and their errors, the fitted number of counts in the line including errors and the derived photon fluxes. A suggested identification is also given. A substantial part of the total wavelength range is covered only by one instrument due to failure of one CCD on each RGS, and because of the gaps between adjacent CCDs. For lines in these regions we give the result of the active RGS, for the lines covered by both RGS we summed up the two spectra. For diagnostic purposes the most important lines are the Ly\(\alpha\) and triplet lines of hydrogen-like and helium-like ions. The measurements of these lines for all species detected in the RGS spectrum and in addition the most prominent iron lines are provided in Table 2. We emphasize again the unusual weakness of iron lines as one of the most remarkable features of the X-ray spectrum of TW Hya.

### 3.2. Line Temperatures

For the elements neon, oxygen and nitrogen both the Ly\(\alpha\) emission lines at 12.1 Å, 19.0 Å, and 24.8 Å respectively, and the He-like resonance lines at 13.5 Å, 21.6 Å, and 28.8 Å respectively are detected in our RGS spectra. In Fig. 3 we plot the expected energy flux ratio from the H-like Ly\(\alpha\) and He-like resonance lines for neon (dotted line), oxygen (solid line) and nitrogen (dashed line) versus logarithmic temperature using the CHIANTI calculations (Dere et al. 1997). We also indicate the measured line ratio range for neon (upright shading), oxygen (right tilted shading) and nitrogen (left tilted shading). These line ratios clearly correspond to effective “isothermal” temperatures, which, however, are independent of abundance. For oxygen and nitrogen these temperatures agree at \(\log T [K] \approx 6.45\), for neon a slightly larger effective temperature is found. The X-ray spectrum of TW Hya does not contain any strong high temperature lines despite its large overall X-ray luminosity. Thus we conclude that most of the observed line emission seems to be produced by material located at pretty much the same temperature. In fact, we verified that a 1-T thermal model (VMEKAL) with free abundances can provide an acceptable description of the RGS spectrum (\(\chi^2_{\text{red}} = 1.36\) for 2333 d.o.f.).

However, one needs to keep in mind that the RGS effective area decreases rapidly at wavelengths below \(\sim 10\ \text{Å}\), i.e. energies above 1.2 keV. Elements such as Mg and Si have their characteristic He-like and H-like line transitions in this wavelength region. In the RGS spectrum of TW Hya these lines remain undetected because of lacking SNR, but this critical spectral region can be studied with EPIC at medium resolution (see Sect. 4). The EPIC spectrum does also show a high-energy tail that cannot be explained by the rather low plasma temperatures dominating the RGS line emission (cf., Sect. 4 and Fig. 4).

---

**Fig. 3.** Temperature dependence of the $Ly_α/r$ line ratio for neon (dotted line), oxygen (solid line), and nitrogen (dashed line) according to the CHIANTI code ([Dere et al. 1997](#)). The ratios observed in the RGS spectrum of TW Hya are indicated by the shaded patterns. All observed values are compatible with a 2 – 3 MK hot isothermal plasma.

### 3.3. Differential Emission Measure

In order to quantify a differential emission measure (DEM) distribution we adopted the following approach; see also [Schmitt & Ness 2004](#) for more details on this DEM reconstruction method. We first introduced a fixed temperature grid located at grid points $T_1 (i=1,3)$ we assume the presence of some emission measure $EM_i$. Denoting the elements carbon ($j=1$), nitrogen ($j=2$), oxygen ($j=3$) and neon ($j=4$) with the index $j$, we can then compute the line emissivities $P_{H,i,j}$ and $P_{He,i,j}$ for the hydrogen- and helium-like lines of the elements $j$ for the temperature components $i$. The observed line ratios $ρ_{obs,j}$ ($j=2,4$) can then be modelled as

$$ρ_{mod,j} = \frac{\sum_{i=1}^{3} EM_i \cdot P_{H,i,j}}{\sum_{i=1}^{3} EM_i \cdot P_{He,i,j}}$$

and we seek a best fit set of the emission measures $EM_i$, through minimizing

$$χ^2 = \sum_{j=2}^{4} \frac{(ρ_{obs,j} - ρ_{mod,j})^2}{(σ_j)^2},$$

where $σ_j$ denotes the error of the line ratio $j$. Clearly, since we are dealing with line ratios of the same elements, the normalization can be set arbitrarily (we chose $EM_1 = 1$). The thus derived EM-distribution is abundance independent. The best fit values for the (relative) values of $EM_i$ are found to be $[1.0, 2.35, 0.59]$. This choice of emission measure reproduces the observed line ratios extremely well ($χ^2_{red} ≈ 0.5$). However,
Table 3. Best fit parameters for the X-ray spectrum of TW Hya described by a multi-temperature thermal model (VMEKAL) including photo-absorption ($N_H = 2 \times 10^{20}$ cm$^{-2}$). The electron density was fixed to $5 \times 10^{12}$ cm$^{-3}$. Elements not listed below are irrelevant in this spectrum, and their individual abundances were held fixed at the solar value. The temperatures and the coupling between some parameters were pre-determined by the analysis of the emission lines seen in the RGS spectrum. Values for the abundances are given with respect to the coupling between some parameters were pre-determined below are irrelevant in this spectrum, and their individual abundances were held fixed at the solar value. The temperatures and the coupling between some parameters were pre-determined by the analysis of the emission lines seen in the RGS spectrum. Values for the abundances are given with respect to the solar absorption towards TW Hya – we find with this procedure the values $C/O = 1.07$, $N/O = 3.15$, $Ne/O = 9.77$ and $Fe/O = 0.91$ with respect to cosmic abundances. Realistic abundance errors are difficult to determine. We estimate abundance errors of about 20% for neon, and about 30% for carbon, nitrogen and iron.

| Parameter | param. coupling | param. value | param. coupling | param. value |
|-----------|----------------|--------------|----------------|--------------|
| $C$       | $= 1.07 \times O$ | $= 0.28$ | $= 1.07 \times O$ | $= 0.40$ |
| $N$       | $= 3.14 \times O$ | $= 0.82$ | $= 3.14 \times O$ | $= 1.18$ |
| $O$       |              | $= 0.26$ |              | $= 0.37$ |
| $Ne$      |              | $= 3.15$ |              | $= 3.97$ |
| $S$       |              | $= 0.0$  |              | $= 0.0$  |
| $Mg$      |              | $= 1.0$  |              | $= 0.65$ |
| $Si$      |              | $= 1.0$  |              | $= 0.13$ |
| $Fe$      |              | $= 0.26$ |              | $= 0.24$ |
| $\log T_1$ |              | $= 6.3$  |              | $= 6.3$  |
| $\log T_2$ |              | $= 6.5$  |              | $= 6.5$  |
| $\log T_3$ |              | $= 7.3$  |              | $= 7.3$  |
| $\log EM_1$ | $= 52.64$ |              | $= 52.55$ |              |
| $\log EM_2$ | $= 53.01$ | $= 3.35 \times EM_1$ | $= 52.90$ |              |
| $\log EM_3$ | $= 52.41$ | $= 0.59 \times EM_1$ | $= 52.53$ |              |

$\chi^2_{\text{red}}$ (d.o.f.) 2.79 (233) 2.61 (232)

given the ill-conditioned nature of the reconstruction problem, other choices of the EM-distribution also provide statistically acceptable fits. With the thus derived set of best fit $EM_i$ values we can choose the normalization to reproduce, say, the oxygen $Ly_\alpha$ line fluxes. Then we use this normalization to determine abundances of carbon, nitrogen, neon and iron relative to oxygen by forcing agreement between predicted and measured fluxes in the observed lines. Note that for carbon and iron we can only use the $Ly_\alpha$ line (for carbon) and the Fe XVII 17.07 $\AA$ line (for iron). Using an interstellar hydrogen column density of $N_H = 2 \times 10^{20}$ cm$^{-2}$ – which is required for a good fit of the EPIC data and is in agreement with the expected interstellar absorption towards TW Hya – we find with this procedure the values $C/O = 1.07$, $N/O = 3.15$, $Ne/O = 9.77$ and $Fe/O = 0.91$ with respect to cosmic abundances. Realistic abundance errors are difficult to determine. We estimate abundance errors of about 20% for neon, and about 30% for carbon, nitrogen and iron.

4. EPIC medium resolution spectrum: EPIC

The count rate spectrum of each EPIC MOS detector was extracted from the area described in Sect. 2. We extracted and analysed the EPIC spectra with SAS version 5.4.1. Individual redistribution matrices and an ancilliary response file were generated in the course of our data reduction process. The combination of these two files fully models the instrumental response.

The EPIC spectrum has a pronounced peak at $E \sim 0.91$ keV or 13.6 $\AA$. Since we know from the XMM-Newton RGS spectrum that both the continuum and iron line emissions are weak, we conclude that this spectral bump must represent emission from H- and He-like neon. This remarkable feature is not observed in EPIC data of other young stars (see e.g. Güdel et al. 2001 [Stelzer et al. 2002 [Stelzer & Neuhäuser 2001b]), emphasizing the peculiar nature of the X-ray spectrum of TW Hya.

Approximating the MOS spectra by a sum of three thermal models with fixed values of temperature and based on the parameters derived from the line analysis, we verify that the temperature and abundance structure derived from the analysis of individual emission lines also provides a consistent description of the medium-resolution data. In this global fit to the MOS spectrum an absorption term with atomic cross-sections of Morrison & McCammon (1983) and $N_H = 2 \times 10^{20}$ cm$^{-2}$ is applied to describe the effects of inter- and/or circumstellar cold gas. The electron density was set to $5 \times 10^{12}$ cm$^{-3}$ following the result of our line-based density analysis (see Sect. 5.2) and kept fixed. We restricted our modeling to the 5.5–40 $\AA$ range, and used the VMEKAL code as implemented in XSPEC, version 11.2.0.

We first allowed only the oxygen abundance and the absolute value of the emission measure to vary, i.e., the parameters not constrained by our line modeling. The best fit determined in this fashion results in $\chi^2_{\text{red}} = 3.2$ (235 d.o.f.), and the residuals suggest that a slight adjustment of the abundances may be needed. If we allow the neon and iron abundances to de-couple from the oxygen abundance, the fit improves to $\chi^2_{\text{red}} = 2.8$ (233 d.o.f.). Note that these “new” abundances are still within the errors of the abundances derived from our line-based RGS
analysis. The best fit parameters of this model are summarized in Table 3 (Model A). We point out that we do not derive nitrogen and carbon abundances from the EPIC spectra, because the instrument has little sensitivity in the relevant spectral range. These abundances are solely derived from the RGS data and – for carbon – are based only on one single line.

Up to this point our fit results are in good agreement with the findings presented by Kastner et al. (2002) from their analysis of the Chandra HETG spectrum of TW Hya, i.e., a strong over-abundance of Ne and emission dominated by low-temperature plasma. Inspection of the EPIC fit residuals does however show clear discrepancies between the EPIC data and model at \(\lambda < 14\,\text{Å}\), where the H-like \(Ly\alpha\) and He-like triplet transitions of magnesium and silicon are located. In particular, two bumps in the model come from emission of Si XIV and Mg XII without any counterpart in the data. Therefore we allowed for adjustment of the Mg and Si abundances in the spectral fitting process. Since any changes in the Mg and Si abundances will be compensated for by changes in \(EM_3\), we must also let vary \(EM_3\). The resulting best fit models have magnesium and silicon abundances well below solar values with a best-fit \(\chi^2_{\text{red}}\) of 2.61. The 90% error contour of the magnesium is at 0.94 (w.r.t. solar), and the silicon abundance is definitely subsolar. A summary of all parameters of this model is given in Table 3 (Model B). In Fig. 4 we show the best fit 3-T model together with the MOS data. For illustration the sum of the two low-energy components and the high-energy component are also plotted separately.

In order to point out the effects of changing Si and Mg abundances we consider only the range between \(5.5 - 12\,\text{Å}\). In Fig. 5 we confront the two models from Table 3 in this wavelength interval with each other. Clearly the fit with free abundances describes the EPIC data far better than assuming solar abundances we consider only the range between \(5.5 - 12\,\text{Å}\). The \(\chi^2_{\text{red}}\) decreases from 1.23 (102 d.o.f.) for the model with solar Mg and Si to 0.90 (101 d.o.f.) for the model where Mg and Si are free parameters, leading to subsolar abundances for both elements.

As a final consistency check of our procedure we now folded back the best fit model B with the response of the RGS. The result is overplotted on the RGS data in Fig. 2. As expected, we find good agreement between model and data. The emission measure of the high-T component is about a factor of three lower than the sum of the two low-T components. This together with its high temperature leads to a very low contribution to the RGS count rate of 0.015 cps (RGS 1) and 0.021 cps (RGS 2), implying that the high-T component is essentially undetectable in the RGS. (The lower count rate in RGS 1 is caused by the missing CCD in the 10 – 14 Å interval.) We thus conclude that the model B described in Table 3 provides an acceptable description of both the XMM-Newton EPIC and RGS spectra.

5. Discussion

So far TW Hya is the only cTTS, i.e. a PMS star with strong \(He\alpha\) emission, for which a high-resolution XMM-Newton X-ray spectrum is available. Since in young stars \(He\alpha\) emission is related to accretion TW Hya presents a unique test case for X-ray emission in this early phase of stellar evolution. Furthermore, it is one of the few stars observed with both XMM-Newton and Chandra at high spectral resolution. In the following we discuss the properties of the X-ray emission of TW Hya, and we present a physical scenario explaining it.

5.1. Variability

During the Chandra observation of TW Hya discussed by Kastner et al. (2002) a sharp rise in intensity followed by a nearly linear decay occurred, that the authors interpreted as a flare. We find little evidence for variability in the XMM-Newton observation presented here (acquired \(\sim 1\,\text{yr}\) after the Chandra data). In any case the lightcurve does not carry the clear signatures of a flare, and no change in spectral hardness is observed. Similarly Kastner et al. (2002) found no changes in the spectral parameters during the variable phase of the Chandra observation, very untypical for stellar (flare) activity. The flare-like event in the Chandra observation has a decay time of \(\sim 10\,\text{ksec}\). Assuming a flare loop at \(T \sim 3\,\text{MK}\) (the dominating temperature derived from the X-ray spectrum) that decays through radiative cooling the density should be \(\sim 10^{10}\,\text{cm}^{-3}\). This is in sharp contrast to the result from the analysis of line ratios (see Sect. 5.2), according to which the densities are higher by two orders of magnitude.

We directly compare the emission levels by computing X-ray fluxes for the time-averaged spectrum. From the Chandra HETGS spectrum Kastner et al. (2002) derived an X-ray flux of \(2.5 \times 10^{-3}\,\text{photons cm}^{-2}\text{s}^{-1}\text{keV}^{-1}\) for the 0.45 – 6.0 keV band. Integrating the RGS spectrum in the energy band which comes nearest to the spectral range of the HETGS, i.e. \(5.5 - 27.5\,\text{Å}\) or 0.45 – 2.25 keV, we arrive at a similar value of \(f_{\text{X,RGS,1}} \approx f_{\text{X,RGS,2}} = 2.3 \times 10^{-3}\,\text{photons cm}^{-2}\text{s}^{-1}\) corresponding to

![Fig. 5. Close-up of the EPIC MOS 1 and MOS 2 spectrum of TW Hya in the range 5.5 – 12 Å: top - Model (A) from Table 3, Mg and Si abundance fixed to solar; bottom - Model (B) from Table 3, Mg and Si abundance free parameters resulting in subsolar abundances for both elements.](image-url)
the lines are constant within about a factor of two. The Chandra HETGS-MEG (see Kastner et al. 2002). The lines and use them for plasma diagnostics. The triplets of He-like ions are of particular importance, because ratios between individual emission lines are separated by about one year. All lines are constant within about a factor of two.

\[ L_{X,\text{RGS}} = 1.4 \times 10^{30} \text{erg/s} \] at a distance of 57 pc. This suggests that TW Hya exhibits only moderate long-term variability.

Based on the small amplitude of long-term variations discussed above, comparing fluxes measured for individual emission lines allows to check the calibration of the instruments on both satellites. We observe a trend towards slightly higher fluxes in the RGS as compared to the HETGS (Fig. 6). However, the difference is a factor two at most.

**5.2. Density in the X-ray Emitting Region**

The high-resolution X-ray spectrum obtained with the RGS allows us to measure flux ratios between individual emission lines and use them for plasma diagnostics. The triplets of He-like ions are of particular importance, because ratios between the intensity of resonance \( r \), intercombination \( i \), and forbidden \( f \) line are sensitive to (electron) temperature (through \( G = (f + i)/r \)) and density (through \( R = f/i \)). While the \( G \)-ratio is of limited value for temperature diagnostics, the \( R \)-ratio constitutes a unique tool to probe the electron density in stellar coronae. Although the triplets from silicon (Si XIII) to nitrogen (NVII) fall in the spectral range of the RGS, in TW Hya only three elements – nitrogen, oxygen, and neon – show sufficient emission in the respective transitions of their He-like ions to warrant analysis.

In Fig. 7 we zoom in on the spectral region around the oxygen and neon triplets of TW Hya overlaying the data with our line fit result. For the modeling of both triplets we used three Lorentzians representing the \( r \), \( i \), and \( f \) lines. Some caution is in order when interpreting the spectrum near the position of the Ne IX triplet: the triplet is not fully resolved in the RGS, and is known to form a blend with a number of iron lines, predominantly a Fe XIX line at 13.53 Å that contaminates the Ne intercombination line. However, we performed fits of the neon triplet including iron and find undistinguishable results. Since we find little hints for the presence of Fe XIX (and generally any iron) in the RGS spectrum (e.g. the lines at 13.80 Å and 14.66 Å are not seen) we assume that iron contamination plays only a minor role and can be neglected.

The remarkable feature of the He-like triplets of TW Hya is the weakness of the forbidden lines. In the LETGS and RGS spectra of all late-type stars observed so far the forbidden lines are always stronger than the intercombination line (in oxygen and neon) and in many cases the measurements are consistent with the so-called low-density limit (e.g. Ness et al. 2001, Ness et al. 2002, Stelzer et al. 2002). This is definitely not the case for TW Hya. We note in particular that with TW Hya being rather cool (spectral type K7; Rucinski & Krautter 1983) the low intensity of the forbidden line cannot be attributed to UV radiation at the wavelengths corresponding to the \( f \rightarrow i \) transitions (Costa et al. 2000). Instead it is a direct indicator of high densities. The formally derived \( f/i \)-value for O VII is \( R_{O VII} < 0.16 \), i.e., only an upper limit can be given due to the weakness of the O VII \( f \)-line. Comparing our measurements to recent calculations by Porquet et al. (2001) without any radiation field we find a lower limit on the density of \( n_{e, O VII} > 1 \times 10^{12} \text{cm}^{-3} \). This is corroborated by the low flux of the nitrogen forbidden line which is only marginally detected (cf., Table 3). The \( R \)-ratio for neon \( R_{Ne IX} = 0.47 \pm 0.11 \) indicates a density of \( n_{e, Ne IX} \sim 1 \times 10^{13} \text{cm}^{-3} \). Inclusion of the Fe XIX blend in the fit of the neon triplet would lower the strength of the \( i \) line, and lead to a somewhat higher value for \( R_{Ne IX} = 0.62 \pm 0.12 \), and subsequently lower density. However the numbers are compatible with the ones cited above within the statistical uncertainties.

The densities derived from the oxygen and neon triplets are at least two orders of magnitude above typical coronal densities. Our density measurements thus fully confirm the results derived by Kastner et al. (2002) from their HETGS spectrum, and we conclude in particular that the high densities cannot be a result of the flaring reported by Kastner et al. (2002) in their Chandra data.

**5.3. Elemental abundances**

The XMM-Newton RGS spectrum as well as our spectral fits to the EPIC spectrum show the X-ray emission of TW Hya clearly dominated by neon emission in agreement with Kastner et al. (2002). Our results specifically suggest a neon abundance significantly enhanced with respect to the solar value \( (Ne \sim 4 N_{e, \odot}) \), while iron and oxygen, the elements with the largest number of lines in the sensitive region of the XMM-Newton and Chandra instruments, are underabundant with respect to solar values, again in agreement
B. Stelzer and J. H. M. M. Schmitt: X-ray emission from an accretion shock on TW Hya

Fig. 7. He-like triplets of Ne IX and O VII measured with the RGS together with best fit Lorentzians. The continuum close to each triplet is approximated by a straight horizontal line. The intensity enhancement to the right of the Ne IX triplet in the RGS spectrum is due to Fe XVII. But the major contamination of the Ne IX triplet is expected to come from a Fe XIX line which is unresolved from the triplet intercombination line (see text in Sect. 5.2).

with Kastner et al. (2002). For the elements silicon, magnesium, and nitrogen (Kastner et al. 2002) claim solar abundances, while carbon lines were not covered by the HETGS spectrum. Interestingly, the lines of He-like and H-like silicon are clearly visible in the HETGS spectrum of TW Hya (cf., Fig. 2 in Kastner et al. 2002), while the same authors note “a curious lack of Mg features, relative to the [i.e. their] model.” While the RGS spectra are not sufficiently sensitive in the relevant spectral region, the EPIC spectrum clearly suggests subsolar abundances also for magnesium and silicon.

Let us now focus on the line emission from neon, oxygen, nitrogen, and carbon as seen by the RGS. Our spectral analysis both with RGS and EPIC shows that very little low temperature material (with \( \log T \,[K] \) < 6.3) can be present. Ness et al. (2002) report photon flux ratios for \( L_{\lambda}/r \) of 0.59 (oxygen) and 0.94 (nitrogen) for the low-temperature F-star Procyon, and 1.87 (oxygen) and 3.26 (nitrogen) for the higher-temperature K-star τ Eri, which must be compared to the values of 1.75 (oxygen) and 4.07 (nitrogen) measured for TW Hya despite its overall low temperature. Although DEM distributions are typically not unique because of the ill-defined nature of the inversion problem, we want to emphasize that the peculiar chemical abundances of TW Hya are not caused by our choice of the EM distribution. For this we examined the energy flux ratio between the \( L_{\lambda}/r \) lines of C VI and N VII as a function of temperature and find that this line ratio can not be explained by any single temperature or combination of temperatures under the assumption of solar abundances for both elements (Fig. 8a). Therefore nitrogen must be overabundant relative to carbon (and also oxygen) with respect to the solar abundance ratio, again in accordance with our fit results. We then investigated the flux ratio between the \( r \) line of neon and the oxygen \( L_{\lambda}/r \) line in the same way (Fig. 8b), and again the observed flux ratio can not be reproduced by any single temperature or combination of temperatures if the abundances were solar, implying that neon must be overabundant compared to oxygen with respect to solar abundances, as found in our fit results. Finally, inspecting the flux ratio between the C VI \( L_{\lambda}/r \) line and the O VII \( r \) line we find perfect consistency assuming the C/O ratio being solar. Since our EPIC results suggest that silicon, magnesium, iron, and oxygen all have similar abundance (with the possible exception of magnesium) we thus conclude that the elemental abundances of these elements as well as that of carbon are reduced with respect to solar values by about a factor of \( 3 \). Nitrogen is enhanced with respect to these elements by a factor of \( 3 \) as evidenced by the XMM-Newton RGS spectrum, and neon is enhanced by a factor of \( 10 \) as evidenced by both the XMM-Newton RGS and EPIC spectra.

5.4. Interpretation

The three properties distinguishing the X-ray spectrum of TW Hya from that of “normal” late-type stars are (1) the absence of a hot component with large emission measure, (2) the high density of the X-ray emitting region, and (3) the peculiar elemental composition, and in particular the low abundance of iron. The first two properties can be naturally explained by at-
tributing the X-ray emission to an accretion shock, the third by the specific environment of TW Hya.

Employing the strong shock formula

$$T = \frac{3\mu m_{H}V_{\text{pre}}^{2}}{16kL}$$

with $\mu$ denoting the mean molecular weight, $m_{H}$ the hydrogen atom mass, and $k$ Boltzmann’s constant, we can convert the measured temperature $\text{lg} T [K] = 6.45$ to an infall preshock velocity $V_{\text{pre}}$ of about $350/\sqrt{(\mu)} \text{ km/s}$. The preshock particle density $n_{\text{pre}}$ should be one fourth of the measured post shock density $n_{\text{post}}$, i.e., $2.5 \times 10^{12} \text{ cm}^{-3}$. In order to estimate $L_{\text{post}}$, the thickness of the postshock cooling layer, we equate the infalling kinetic energy flux with the radiated energy flux ($\text{Lamzin 1995}$) through

$$\frac{\mu m_{H}n_{\text{pre}}V_{\text{pre}}^{3}}{2} = n_{\text{post}}^{2}\Lambda_{\text{mean}}L_{\text{post}}.$$  

Here $\Lambda_{\text{mean}}$ denotes the total mean radiative post shock cooling rate per unit emission measure. Denoting $\Lambda_{\text{mean}}$ in units of $10^{-23} \text{ erg cm}^{-2} \text{ s}^{-1}$, we derive

$$L_{\text{post}} = \frac{9 \times 10^{7}}{\sqrt{\mu}} (\Lambda_{\text{mean,23}})^{-1} \text{ [cm]}.$$  

For an isothermal cosmic abundance plasma at $\text{lg} T [K] = 6.45$ $\Lambda_{\text{mean,23}}$ is generally close to unity; if we assume $\Lambda_{\text{mean,23}} = 0.3$ because of the depleted elemental abundances and $\mu = 1.5$, the post-shock thickness is $L_{\text{post}} \approx 2500 \text{ km}$ with admittedly considerable uncertainty. Using the observed O VIII energy flux of $3.2 \times 10^{-15} \text{ erg/cm}^{-2}/\text{s}$ and an assumed O VIII $L_{\text{Ly} \alpha}$ cooling function of $9.6 \times 10^{-25} \text{ erg cm}^{-3} \text{ s}^{-1}$ (assuming $\text{lg} T [K] = 6.45$ and an oxygen depletion of 0.3) we compute an overall volume emission measure of $EM = 1.3 \times 10^{53} \text{ cm}^{-3}$ at the distance of 57 pc. Since $n_{\text{post}} \approx 10^{13} \text{ cm}^{-3}$, the emitting volume $V_{\text{emit}}$ must be $V_{\text{emit}} = 1.3 \times 10^{27} \text{ cm}^{3}$. The shock area $A_{\text{shock}}$ then becomes $A_{\text{shock}} = V_{\text{emit}}/L_{\text{post}} = 5.1 \times 10^{18} \text{ cm}^{2}$, which would constitute only a very tiny fraction of the visible stellar surface ($< 0.01 \%$). Clearly, these estimates are by necessity very rough, but in qualitative agreement with previous observations in other wavelengths: $\text{Muzerolle et al. 2002}$ have shown that the shape of the optical/UV spectral energy distribution of TW Hya can be explained by an accretion shock which fills ~ 0.3% of the stellar surface, and small accretion shocks are also found on other T Tauri stars ($\text{Calvet & Gullbring 1995}$). Computing the mass accretion rate in the funnel flow through $M_{\text{acc}} = 1/4A_{\text{shock}}n_{\text{post}}\mu m_{H}V_{\text{pre}},$ we find $M_{\text{acc}} \approx 1 \times 10^{-11} \text{ M}_{\odot}/\text{yrs}$, which is entirely plausible and within one order of magnitude of the mass accretion rate of TW Hya derived from UV data ($\text{Muzerolle et al. 2002}$).

What kind of material is flowing through this funnel onto TW Hya? We have shown that this material is in general metal-depleted in particular with respect to grain-forming elements such as Mg, Si, Fe, C and O. Overabundances of neon are found in stellar coronae of RS CVn systems ($\text{Audard et al. 2003}$), and nitrogen overabundances in evolved stars ($\text{Schmitt & Ness 2002}$). The low abundances especially of iron and carbon call for a different explanation for these chemical peculiarities. TW Hya is rather young and formed “just recently” out of a molecular cloud. Models of cloud chemistry at high densities ($n > 10^{7} \text{ cm}^{-3}$) predict that almost all metals condense into grains except nitrogen ($\text{Charnley 1997}$). If the remaining depleted gas is then decoupled from the grains in an accretion disk around a young star (as is expected in planetary formation models), the accreted and shock-heated gas is expected to be metal-deficient as well. Indeed, $\text{Weinberger et al. 2002}$ found evidence for the presence for condensed silicates in the disk of TW Hya, and $\text{Herczeg et al. 2002}$ speculated about a deficiency of Si in the accretion flow of TW Hya based on the examination of its far-UV spectrum. XMM-Newton has completed this picture of TW Hya as an accreting PMS star, and for the first time provided a consistent view of X-ray emission from a stellar accretion shock by observation.

6. Summary

To summarize, the marked differences between the X-ray properties of TW Hya and active main-sequence dwarf stars suggest either (i) strong evolutionary effects on coronal structures, or (ii) an entirely different origin for the X-ray emission of TW Hya. X-ray emission from a shock at the bottom of an ac-
cretion column provides a plausible mechanism for the latter possibility. The derived shock temperatures, gas densities, filling factors and mass accretion rates as well as the obvious lack of grain-forming elements in the X-ray emitting region provide strong indications in favor of this scenario.

A high-resolution X-ray spectrum of another member of the TW Hya association, HD 98800, was recently obtained with Chandra (CXC Press Release 03-04). The object is a quadruple star with a circumbinary disk. In terms of Hα emission HD 98800 is a wTTS. Therefore it does not come as a surprise that its X-ray properties are very different from those of TW Hya, and clearly reminiscent for typical stellar activity. Similarly, the high-resolution X-ray observation of PZ Tel, a ∼20 Myr old post-TTS in the Tucanae association, does not show properties dramatically different from older late-type stars (Argiroffi et al., in prep.).

We conclude that TW Hya stands out as a presently unique example for a star with strong evidence for accretion signatures in its X-ray spectrum. Future high spectral resolution and high sensitivity X-ray observations will have to show whether soft emission, high densities, and metal-deficiency are general characteristics of cTTS.
