We present a theoretical and numerical study of the self-steepening and shock formation of large-amplitude dust ion-acoustic waves (DIAWs) in dusty plasmas. We compare the non-dispersive two fluid model, which predicts the formation of large amplitude compressive and rarefactive dust ion-acoustic (DIA) shocks, with Vlasov/fluid simulations where ions are treated kinetically while a Boltzmann distribution is assumed for the electrons.

Shukla and Silin [1] predicted the existence of small amplitude dust ion-acoustic waves (DIAWs) in an unmagnetized dusty plasma. In the DIAWs, the restoring force comes from the pressure of inertialless electrons, while the ion mass provides the inertia to support the waves. On the timescale of the DIAWs, charged dust grains remain immobile, and they affect the overall quasi-neutrality of the plasma. When the dust grains are charged negatively, one has the depletion of the electrons in the background plasma. Subsequently, the phase speed \( \omega/k = (n_{i0}/n_{e0} + 3T_i/T_e)^{1/2}C_s \) where \( n_{i0} \) (\( n_{e0} \)) is the unperturbed ion (electron) number density, \( T_i \) (\( T_e \)) is the ion (electron) temperature, and \( m_i \) (\( m_e \)) is the ion (mass) electron mass. The DIAWs becomes larger than the usual ion-acoustic speed in an electron-ion plasma without negatively charged dust. When \( n_{i0} > n_{e0} \) or \( T_i \gg T_e \), small-amplitude DIAWs do not suffer Landau damping in a plasma, since the increased phase speed is much larger than the ion thermal speed \( (T_i/m_i)^{1/2} \). Small-amplitude DIAWs have been observed in laboratory experiments [2], and the observed phase speed is in an excellent agreement with the theoretical prediction of Ref. [1].

Recently, laboratory experiments [3, 4, 5, 6] have been conducted to study the formation of dust ion-acoustic (DIA) shocks in dusty plasmas. Dust ion acoustic compression pulses have been observed to steepen as they travel through a plasma containing negatively charged dust grains. Theoretical models [3, 5] have been proposed to explain the formation of small amplitude DIA shocks in terms of the Korteweg-de Vries-Burgers equation, in which the dissipative terms comes from the dust charge perturbations [3]. Popel et al. [10] have included sources and sinks in the ion continuity equation, linear ion pressure gradients in the nonlinear ion momentum equation with a model collision term, as well as the dust grain charging equation to study the formation DIA shock-wave structures.

In this Brief Communication, we present analytical and numerical studies of large amplitude DIA shock waves in an unmagnetized dusty plasma [11]. We use fully nonlinear continuity and momentum equations for the warm ion fluid, as well as Boltzmann distributed electrons and the quasi-neutrality condition to examine the spatio-temporal evolution of large amplitude dust ion-acoustic pulses. We find simple-wave solutions of our fully nonlinear two fluid model, and compare them with those deduced from the time-dependent Vlasov simulations which uses initial conditions corresponding to the ones obtained from our theoretical model.

We consider an unmagnetized dusty plasma whose constituents are singly charged positive ions, electrons and charged dust grains. Thus, at equilibrium, the dust grains are assumed to be immobile. The dynamics of low phase speed (in comparison with the electron thermal speed) nonlinear, dust ion-acoustic waves is governed by a Boltzmann distribution for the electrons

\[ n_e = n_{e0} \exp\left(\frac{e\phi}{T_e}\right), \]  

(1)

and the continuity and momentum equations for the ions

\[ \frac{\partial n_i}{\partial t} + \frac{\partial (n_i v_i)}{\partial x} = 0, \]  

(2)

and

\[ \frac{\partial v_i}{\partial t} + v_i \frac{\partial v_i}{\partial x} = -\frac{e}{m_i} \frac{\partial \phi}{\partial x} - \frac{3T_i n_i}{m_i n_{i0}^2} \frac{\partial n_i}{\partial x}, \]  

(3)

where \( n_e \) (\( n_i \)) is the total electron (ion) number density, \( e \) is the magnitude of the electron charge, \( \phi \) is the wave potential, and \( v_i \) is the ion fluid velocity. The system is closed by means of Poisson’s equation

\[ \frac{\partial^2 \phi}{\partial x^2} = 4\pi e (n_e - n_i - eZ_d n_{i0}). \]

In the following, we consider non-dispersive DIAWs, and use the quasi-neutrality condition \( n_e = n_i + \epsilon Z_d n_d \) instead of Eq. (4), together with the normalized variables \( N = n_i/n_a, u = u_i/C_s, \varphi = e\phi/T_e, \tau = r_D^{-1}x \) and \( \tau = \omega_{pi}t \), where \( \omega_{pi} = (4\pi n_0 e^2/m_i)^{1/2} \) is the ion plasma frequency and \( r_D = C_s/\omega_{pi} \) is the electron Debye radius. Thus, the system of equations (1)-(3) can be rewritten as

\[
\frac{\partial u}{\partial \tau} + u \frac{\partial u}{\partial z} + \left( \frac{1}{N + \alpha - 1} + 3\eta N \right) \frac{\partial N}{\partial z} = 0, \tag{5}
\]

and

\[
\frac{\partial N}{\partial \tau} + N \frac{\partial u}{\partial z} + u \frac{\partial N}{\partial z} = 0, \tag{6}
\]

where \( \alpha = n_a/n_d \) and \( \eta = T_0/T_e \). In obtaining Eq. (5), we have used \( \varphi = \ln[(N + \alpha - 1)/\alpha] \) which follows from Eq. (1) and the quasi-neutrality condition.

In order to study the nonlinear evolution of large amplitude DIAWs, we seek simple wave solutions [12] of Eqs. (5) and (6). For this purpose, we rewrite them in the matrix form as

\[
\frac{\partial}{\partial \tau} \begin{bmatrix} u \\ N \end{bmatrix} + \begin{bmatrix} u - 3\eta N \\ N \end{bmatrix} \frac{\partial}{\partial z} \begin{bmatrix} u \\ N \end{bmatrix} = \begin{bmatrix} 0 \\ 0 \end{bmatrix}. \tag{7}
\]

Here, the nonlinear wave speeds are given by the eigenvalues

\[
\lambda_{\pm} = u \pm N^{1/2} \left( \frac{1}{N + \alpha - 1} + 3\eta N \right)^{1/2}, \tag{8}
\]

of the square matrix multiplying the second term in Eq. (7). The square matrix in Eq. (7), which we denote \( A \), can be diagonalized by a diagonalizing matrix \( C \) whose columns are the eigenvectors of \( A \), so that

\[
C^{-1} AC = \Lambda \equiv \begin{bmatrix} \lambda_+ & 0 \\ 0 & \lambda_- \end{bmatrix}, \tag{9}
\]

where

\[
C = \begin{bmatrix} 1 & 1 \\ \frac{1}{N(N + \alpha - 1) + 3\eta} & \frac{1}{N(N + \alpha - 1) + 3\eta} \end{bmatrix}^{-1/2}, \tag{10}
\]

and

\[
C^{-1} = \begin{bmatrix} \frac{1}{2} & \frac{1}{2} \\ \frac{1}{2} & -\frac{1}{2} \end{bmatrix} \left( \frac{1}{N(N + \alpha - 1) + 3\eta} \right)^{1/2}, \tag{11}
\]

Multiplying Eq. (7) by \( C^{-1} \) from the left gives the diagonalized system of equations

\[
\frac{\partial \psi_+}{\partial \tau} + \lambda_+ \frac{\partial \psi_+}{\partial z} = 0, \tag{12}
\]

and

\[
\frac{\partial \psi_-}{\partial \tau} + \lambda_- \frac{\partial \psi_-}{\partial z} = 0, \tag{13}
\]

where the new variables are

\[
\psi_{\pm} = u \pm \frac{1}{2} \int_1^N \left( \frac{1}{N'(N' + \alpha - 1) + 3\eta} \right)^{1/2} dN'. \tag{14}
\]

Equations (12) and (13) describe the DIAWs propagating in the positive and negative \( z \) directions, respectively. Setting \( \psi_- \) to zero, we have

\[
u(N) = \int_1^N [1/N'(N' + \alpha - 1) + 3\eta]^{1/2} dN', \tag{15}
\]

which inserted into Eq. (12) gives

\[
\lambda_+(N) = \int_1^N \left( \frac{1}{N'(N' + \alpha - 1) + 3\eta} \right)^{1/2} dN' + N^{1/2} \left( \frac{1}{N + \alpha - 1} + 3\eta \right)^{1/2} \tag{16}
\]

Since \( \psi_+ \) can be written as a function of \( N \), Eq. (12) holds also for \( N \), i.e.

\[
\frac{\partial N}{\partial \tau} + \lambda_+(N) \frac{\partial N}{\partial z} = 0, \tag{17}
\]

which, as long as \( N \) is continuous, has the general solution \( N = f_0(x) \), where \( x = x - \lambda_+(N)t \) and \( f_0 \) is the initial condition for \( N \). We have plotted \( \lambda_+ \) as a function of \( N \) in Fig. 1. Here, we see that \( \lambda_+ \) grows with increasing \( N \) in the two cases with \( \alpha = 0.25 \). In the case
with \( \lambda = 0.05 \), however, the phase speed first decreases for \( N \approx 1 \) before increasing with increasing \( N \). In the small-amplitude limit, \( N = 1 + N_1 \), where \( |N_1| << 1 \), we have the first-order Taylor expansion \( \lambda_+ = c + \gamma N_1 \), where \( c = (1/\alpha + 3\eta) / 2 \) is the linear acoustic speed and \( \gamma = (3\alpha + 12\eta) / 2\alpha(\alpha + 3\eta) / 2 \) is the coefficient in front of the nonlinear term. We note that \( \gamma \) is negative for sufficiently small \( \alpha \) (in agreement with the \( \alpha = 0.05 \) case displayed in Fig. 1), and in the cold ion limit \( \eta = 0 \) we recover the result that \( \alpha < 1/3 \) leads to a negative coefficient \( \delta \) in front of the nonlinear term. The linear acoustic speed increases when \( \alpha \) decreases. Thus, in the presence of negatively charged dust, the phase speed of the waves may become much larger than the ion acoustic speed, so that the Landau damping of the waves decreases.

In order to compare the fluid and kinetic theories, we have solved the coupled Eqs. (5) and (6) numerically and compared the results with numerical solutions of the Vlasov equation. As an initial condition for our fluid simulations, we take a large-amplitude localized density pulse, \( N = 1.5 - 0.5 \text{sech}^2(3 \sin(2\pi z/20000) + 1.5) \), while the initial condition for the velocity is obtained from the simple wave solution as \( u(N) = \int_{-\infty}^{\infty} \frac{1}{N'}(N' + \alpha - 1) + 3\eta) / 2 N' \) d\( N' \). The results are compared with numerical solutions of the ion Vlasov equation

\[
\frac{\partial f}{\partial t} + v \frac{\partial f}{\partial z} + \frac{\partial \varphi}{\partial z} \frac{\partial f}{\partial v} = 0, \tag{18}
\]

where \( v \) has been normalized by \( C_s \) and the ion distribution function \( f \) by \( n_{i0}/C_s \). Here, we have also used the quasineutrality condition and thus \( \varphi = \ln[(N+\alpha-1)/\alpha] \), where \( N = \int_{-\infty}^{\infty} f \, dv \). For the initial condition, we are using the shifted Maxwellian ion distribution function

\[
f(z, v) = \frac{N(z)}{\sqrt{2\pi T(z)}} \exp\left[-\frac{|v - u(z)|^2}{2\eta T(z)}\right], \tag{19}\]

where we are using the same initial condition for the density \( N \) and the velocity \( u \) as in the fluid simulations. For the scaled (by \( T_{i0} \)) ion temperature \( T \), we obtain an initial condition by combining the ideal gas law \( P = NT \), where \( P = P_i / P_{i0} \) is the normalized ion pressure and the adiabatic law \( P = N^3 \), giving the initial condition \( T = N^2 \).

In Fig. 2, we present a comparison between the density profiles obtained from the fluid and Vlasov simulations, at different times. In the upper panel, the ion-electron temperature ratio \( \eta = 0.1 \), and the electron-ion density ratio \( \alpha = 0.25 \). We see that both the fluid (left) and Vlasov (right) solutions exhibit shocks, where the shock front is distinct in the fluid solution and more diffuse in the Vlasov solution. The corresponding ion distribution function is displayed in Fig. 3. We observe that the formation of the shock at \( t = 3400 \) is located at \( z \approx 7000 \). It is associated with a “kink” in the distribution function. A population of ions have also been accelerated by the shock. The middle panels of Fig 2 are for \( \eta = 0.1 \) and \( \alpha = 0.25 \). Here, the fluid solution exhibits clear shocks, while the Vlasov simulation shows only a phase of self-steepening at \( t = 500 \), followed by an expansion of the diffuse shockfont at \( t = 1000 \). The ion distribution function in Fig. 4 shows that the shockfront is strongly Landau damped for this case. Finally, the bottom panels of Fig. 2 show results for \( \alpha = 0.05 \) and \( \eta = 1 \). In this
case, the fluid solution again shows a shock in the front end of the pulse, but also the rear end of the shock steepens, which can be seen at \( z \approx -6000 \) for \( t = 1000 \). The steepening of the pulse for low-amplitude density perturbations in the rear of the pulses can be explained by that the wave speed decreases for small-amplitude density perturbations \( (N < 1.1) \), as seen in Fig. 1, while it increases again for large-amplitude density perturbations. The Vlasov solution again shows a diffusive shock in the front, while it reproduces the steepening of the density in the rear of the pulse. In the middle panel of Fig. 5, the ion distribution function shows the self-steepening phase of the shockfront, and the lower panel shows the diffusion of the shock by shock-accelerated ions. In the rear end of the pulse, the distribution function forms a “kink,” clearly seen at \( z \approx -6000 \) in the bottom panel.

We have also performed simulations with smaller amplitudes of the pulses (not shown here) and they exhibit essentially the same behavior as in the large-amplitude case. It is interesting to note that it is the strongly heated and shock-accelerated ions in the pulse that leads to Landau damping by overtaking the pulse. The heating of the ions is due to adiabatic compression, leading to a higher thermal speed of the ions inside the pulse than in the equilibrium plasma. Another effect is that the fluid (mean) velocity of the ions further accelerates the ions. For Landau damping to be unimportant, we thus have the condition that the wave speed must be much larger than the sum of the ion thermal and fluid velocities. Inserting Eqs. (15) and (16) into the inequality \( \lambda_+ > V_T + u \), where the scaled ion thermal speed \( V_T = (\eta T)^{1/2} = \eta^{1/2} N \), we obtain the condition \( N^{1/2}[1/(\alpha - 1) + 3\eta N]^{1/2} \gg (\eta N^2)^{1/2} \), or \( (1/(\alpha - 1)N\eta) + 3^{1/2} \gg 1 \). This condition is fulfilled if \( \eta \ll 1 \) (leading to the sharp shock seen in Fig. 3 and the upper right panel of Fig 2) or/and if the electrons are evacuated due to the dust so that \( \alpha \ll 1 \), and at the same time \( N \approx 1 \). The latter corresponds to the case where the sign of the coefficient in front of the low-amplitude nonlinear term becomes negative, so that there will be a shock in the rear end of the pulse while the front of the shock expands, in agreement with the observations in Fig. 5 and lower right panel of Fig 2. The expansion of the shockfront at high dust densities has also been observed in the experiment.

To summarize, we have presented the dynamics of fully nonlinear, nondispersive dust ion acoustic waves in an unmagnetized dusty plasma. By using the Boltzmann electron distribution as well as the hydrodynamic equations for the warm ion fluid and quasi-neutrality condition, we have represented the governing equations in the form of a master equation whose characteristics have been found analytically. The fluid equations has been solved to obtain the density and velocity profiles of the DIA shock waves, which exhibit the steepening of the waveforms both in the front and rear depending upon the values of \( \alpha \). We have also compared our theoretical results with those obtained from computer simulations of the time dependent Vlasov equation. The Vlasov solution shows a diffuse shock in the front end of the pulse, due to strong Landau damping, while a sharp shock develops in the rear end of the pulse, similar to the results from the simulation of Eqs. (5) and (6).
