OBJECTIVE Despite tremendous advancements in biomedical science and surgical technique, spine surgeries are still associated with considerable rates of morbidity and mortality, particularly in the elderly. Multiple novel techniques have been employed in recent years to adequately treat spinal diseases while mitigating the perioperative morbidity associated with traditional spinal surgery. Some of these techniques include minimally invasive methods and novel anesthetic and analgesic methods. In recent years, awake spine surgery with spinal anesthesia has gained attention as an alternative to general anesthesia (GA). In this study, the authors retrospectively reviewed a single-institution Egyptian experience with awake spine surgery using spinal anesthesia during the COVID-19 pandemic.

METHODS Overall, 149 patients who were admitted to As-Salam International Hospital in Cairo for lumbar and lower thoracic spine surgeries, between 2019 and 2020, were retrospectively reviewed. Patient demographics and comorbidities were collected and analyzed. Visual analog scale (VAS) and Oswestry Disability Index (ODI) scores were assessed at different time intervals including preoperatively, immediately after surgery, and 1 year postoperatively. Patient satisfaction was queried through a questionnaire assessing patient preference for traditional anesthesia or spinal anesthesia.

RESULTS Of the 149 patients who successfully received spine surgery with spinal anesthesia, there were 49 males and 100 females. The cohort age ranged from 22 to 85 years with a mean of 47.5 years. The operative time ranged from 45 to 300 minutes with a mean estimated blood loss (EBL) of 385 ± 156 mL. No major cardiopulmonary or intraoperative complications occurred, and patients were able to eat immediately after surgery. Patients were able to ambulate without an assistive device 6 to 8 hours after surgery. Decompression and fusion patients were discharged on postoperative days 2 and 3, respectively. VAS and ODI scores demonstrated excellent pain relief, which was maintained at the 1-year postoperative follow-up. No 30- or 90-day readmissions were recorded. Of 149 patients, 124 were satisfied with spinal anesthesia and would recommend spinal anesthesia to other patients. The remaining patients were not satisfied with spinal anesthesia but reported being pleased with their postoperative clinical and functional outcomes. One patient was converted to GA due to the duration of the procedure.

CONCLUSIONS Patients who received spinal anesthesia for awake spine surgery experienced short stays in the hospital, no readmissions, patient satisfaction, and well-controlled pain. The results of this study have validated the growing body of literature that demonstrates that awake spine surgery with spinal anesthesia is safe and associated with superior outcomes compared with traditional GA. Additionally, the ability to address chronic debilitating conditions, such as spinal conditions, with minimal use of valuable resources, such as ventilators, proved useful during the COVID-19 pandemic and could be a model should other stressors on healthcare systems arise, especially in developing areas of the world.

KEYWORDS awake surgery; minimally invasive; case series; Egypt; COVID-19; spine surgery; spinal anesthesia

DESpite tremendous advancements in biomedical science and surgical technique, spine surgeries are still associated with considerable rates of morbidity and mortality, particularly in the elderly. Trials are currently underway that seek to understand significant risk factors and reduce adverse effects associated with spine surgery.1 When seeking to reduce sources of morbidity and mortality, it is critical to ensure safe, efficacious administration of anesthesia. Currently, the most prevalent type of anesthesia used in spine surgery is general anesthesia...
GA is not without its drawbacks, however. These include complications that affect cognition and cardio-pulmonary systems as well as postoperative nausea and vomiting. Thus, recently there has been an increased interest in regional or spinal anesthesia in spine surgery. These techniques may allow faster recovery for patients and are not associated with the same possible complications as GA.

There are considerations that must be taken when contemplating spinal anesthesia. These include issues with redosing, the ability to use neuromonitoring, and cardio-pulmonary concerns when patients are positioned prone. There are also recently emergent advantages to spinal anesthesia. The COVID-19 pandemic has affected the medical landscape in immeasurable ways. One major change has been the need to prioritize ventilators, especially in countries without immense healthcare resources and expenditures. However, despite the pandemic, chronic illnesses such as back pain did not decrease. Thus, there is a need to take care of these patients without overutilizing important resources such as ventilators or putting patients at increased risk of contracting COVID-19. Spinal anesthesia, with its reduced resource footprint, may provide this ability.

There are few large-volume studies on the use of spinal anesthesia for spine surgery. In this study, we retrospectively reviewed a single-institution Egyptian experience with awake spine surgery using spinal anesthesia during the COVID-19 pandemic.

### Methods

We present a case series of 149 patients admitted to As-Salam International Hospital in Cairo, Egypt, for lumbar and lower thoracic spine surgeries between 2019 and 2020. Informed consent was obtained before every procedure and all operations were performed by the same surgical team. Patient demographics and comorbidities are shown in Table 1. A breakdown of the 149 scheduled surgeries is summarized in Table 2. All patients were tested for COVID-19 with the polymerase chain reaction (PCR) test prior to surgery.

Visual analog scale (VAS) and Oswestry Disability Index (ODI) scores were assessed preoperatively, immediately after surgery, and 1 year after surgery. Patient satisfaction was assessed with a simple questionnaire containing the following questions. 1) Would you recommend this type of anesthesia to other patients? 2) If you had the same condition again, would you accept the same type of anesthesia? 3) Would you accept the same type of anesthesia?

### Anesthetic Technique

Standard monitors were applied to the patient in the operating room, and the patient was placed in a lateral position. After sterile preparation and draping of the back, 5 mL to 10 mL of 2% lidocaine was used to infiltrate the third or fourth lumbar intervertebral space. A 25-gauge Sprotte spinal needle was then introduced into the intervertebral space until free flow of cerebrospinal fluid was visualized after removal of the spinal needle stylet. At this time, 3 mL to 5 mL of 0.5% bupivacaine and 0.3 mg of morphine were injected into the spinal canal. The patient was turned supine and remained in this position for 10 minutes.
Case Presentation

A 50-year-old male patient presented with significant left radicular pain that failed to respond to conservative management. Sagittal MR images demonstrated a caudally migrated disc at L5–S1 (Fig. 1), and axial MR images revealed compression of the spinal nerve and dural sac (Fig. 2). After preoperative investigations were completed, including COVID-19 PCR testing, the patient was brought in for surgery. The patient was placed in the lateral decubitus position for spinal anesthesia (Fig. 3) and was able to assist with their own positioning (Fig. 4). The disc fragment compressing the spinal nerve was successfully removed (Fig. 5).

Results

Overall, 149 patients received successful spine surgery under spinal anesthesia. The mean age of our cohort was 47.5 years (22–85 years), and included 49 males and 100 females. The mean estimated blood loss (EBL) across all procedures was $385 \pm 156$ mL, and the operative time ranged from 45 to 300 minutes. Under spinal anesthesia, the patients were able to assist with their positioning in the beginning of surgery and were capable of conversation and interaction during surgery. A visually administered, intrathecal injection of an extra dose of spinal anesthesia was necessary for 7 patients. This was possible because the dura mater was exposed for decompression procedures.

Charged on the 2nd postoperative day, and fusion and revision patients were discharged on the 3rd postoperative day.

Patients demonstrated excellent postoperative pain relief, as measured by VAS and ODI scores, which was maintained and improved at the 1-year postoperative follow-up (Table 3). There were no 30- or 90-day readmissions. There were no cases of patients contracting COVID-19 in the perioperative setting.

Of 149 patients, 124 were satisfied with spinal anesthesia and would recommend spinal anesthesia to another patient. The remaining 25 patients, while not satisfied with spinal anesthesia, were still pleased with their postoperative clinical and functional outcomes.

Discussion

When administering anesthesia for spine surgery, robust measures must be taken to ensure patient safety and satisfaction, as well as to reduce postoperative pain and complications. This study demonstrated that patients who underwent spine surgery with spinal anesthesia had better clinical outcomes than those who received GA. These results are consistent with those reported in the literature.

Currently, GA is the most common type of anesthesia used. This might be because spine surgery was previously associated with considerable morbidity, including blood loss, retraction of musculature, and lengthy operative time, necessitating good airway control. Additionally, there was great variance in these features, so prediction of surgery duration and invasiveness was challenging. With newer modern techniques, including minimally invasive surgery and increasing familiarity with spine pathology, spine sur-

The case of a 5-hour, three-level revision, the patient was converted to GA after 3 hours with spinal anesthesia.

There were no major cardiopulmonary complications, and there were no intraoperative complications that affected patient satisfaction. Patients were able to eat immediately after surgery. The mean time to ambulation, with or without use of a walking aid, was 19 ± 7 hours. Patients who underwent fusion were allowed to rest on the 1st postoperative day, with ambulation encouraged on the 2nd postoperative day. Decompression patients were discharged on the 2nd postoperative day, and fusion and revision patients were discharged on the 3rd postoperative day.

Patients demonstrated excellent postoperative pain relief, as measured by VAS and ODI scores, which was maintained and improved at the 1-year postoperative follow-up (Table 3). There were no 30- or 90-day readmissions. There were no cases of patients contracting COVID-19 in the perioperative setting.

Of 149 patients, 124 were satisfied with spinal anesthesia and would recommend spinal anesthesia to another patient. The remaining 25 patients, while not satisfied with spinal anesthesia, were still pleased with their postoperative clinical and functional outcomes.

Surgery has become more controlled, facilitating the use of spinal anesthesia. Spinal anesthesia not only minimizes the cardiopulmonary concerns relevant to GA but also is associated with less postoperative nausea and vomiting, less postoperative narcotic use, and less economic burden. Challenges associated with spinal anesthesia, however, include increased stress on the anesthesiologist and challenges when interpreting postoperative neurological examination results.

The advantages of spinal anesthesia when compared with GA have been researched and reported. Although some studies have found that spinal anesthesia is merely comparable to GA, a large number of studies have found spinal anesthesia is, in fact, superior at providing postoperative pain relief, maintaining hemodynamic stability, and reducing postoperative adverse effects. Randomized controlled trials have demonstrated that spinal anesthesia is associated with reduced postoperative nausea and vomiting, a shorter hospital length of stay, less intraoperative blood loss, reduced changes in heart rate and blood pressure, reduced risk of deep vein thrombosis, superior glycemic control in patients with diabetes, reduced ocular complications, and reduced cost.

There were no anesthetic failures or episodes of airway compromise, desaturation, or cardiovascular instability. The use of spinal anesthesia circumvented the deleterious physiological consequences of prone positioning under GA entirely. It is thought that the maintenance of spontaneous ventilation results in lower intrathoracic pressure and less subsequent distension of the epidural veins, leading to a lower EBL across all procedures. There were no incidences of postdural puncture headache.

**Spine Surgery and the COVID-19 Pandemic**

Spine surgery, and particularly triaging spine surgery, became and remains difficult due to the COVID-19 pandemic. As a result of the pandemic, there have been significant shortages of medications, supplies, and providers. Available resources have been understandably shunted to the front lines of the fight against COVID-19. While urgent spinal surgeries do exist, many spinal surgeries are theoretically “elective.” Therefore, resource management in times of scarcity greatly reduces a medical center’s spine surgery throughput capacity. A prime example of this is Tan Tock Seng Hospital, located in the epicenter of Singapore’s COVID-19 outbreak, which reported a 50% reduction in elective procedures in the first 6 weeks of the outbreak. Many other health systems have placed a block on elective procedures during particularly difficult periods of this pandemic. For these reasons, there have been efforts to establish guidelines for appropriate courses of action given specific surgical spine pathologies. Verification of such guidelines and retrospective analysis will be critical to establish evidence-based systems for spinal care in the event of a future viral outbreak.

There is evidence that awake spine surgery is associated with reduced cost, length of stay, and healthcare resource utilization. Therefore, it is likely that in any potential future setting of medical scarcity, awake spine surgery could increase a medical center’s capacity to perform spinal procedures as it would be associated with less shunting of resources away from the front lines. This phenomenon has been documented in the setting of awake orthopedic surgery programs. In this sense, awake spinal anesthesia has the potential to play a major role in spinal care in the event of a future pandemic.

**Conclusions**

Our study supports the growing precedent that awake lumbar spinal anesthesia is a safe and effective alternative to GA and is associated with fewer intraoperative and postoperative complications, as well as increased patient satisfaction.

| Operative Data | Value | p Value |
|----------------|-------|---------|
| Mean EBL ± SD, mL | 385 ± 156 |       |
| Mean op time ± SD, mins | 128 ± 34 |       |
| Functional outcome, mean ± SD | | |
| Preop VAS score | 7.30 ± 0.89 |       |
| Immediately postop VAS score | 2.08 ± 1.01 | <0.001 |
| 1-yr postop VAS score | 1.90 ± 0.92 | <0.002 |
| Preop ODI score | 44.01 ± 6.78 |       |
| Immediately postop ODI score | 15.30 ± 4.62 | <0.002 |
| 1-yr postop ODI score | 13.5 ± 4.73 | <0.002 |
| Time to ambulation, hrs | 19 ± 7 |       |

**Other clinical outcomes**

|                |       |       |
|----------------|-------|-------|
| Satisfaction w/ anesthesia | 83.2% |       |
| 30-day readmissions | None |       |
| 90-day readmissions | None |       |
| Length of stay, nights |     |       |
| Decompression | 1 |       |
| Fusion | 2 |       |
| Revision | 2 |       |
and surgeon satisfaction. Furthermore, awake spinal anesthesia may play a critical role in maintaining spinal surgical care in potential future pandemics.
