This work introduces a scaffolding framework to compactly parametrise solid structures with conforming NURBS elements for isogeometric analysis. A novel formulation introduces a topological, geometrical and parametric subdivision of the space in a minimal plurality of conforming vectorial elements. These determine a multi-compartmental scaffolding for arbitrary branching patterns. A solid smoothing paradigm is devised for the conforming scaffolding achieving higher than positional geometrical and parametric continuity. Results are shown for synthetic shapes of varying complexity, for modular CAD geometries, for branching structures from tessellated meshes and for organic biological structures from imaging data. Representative simulations demonstrate the validity of the introduced scaffolding framework with scalable performance and groundbreaking applications for isogeometric analysis.

1 INTRODUCTION

Devising an end-to-end framework to trace parametric geometries fully compatible with continuous-domain computational simulations is an extremely complex task, and currently stands as an open challenge. The design of geometrical structures traditionally employs computer-graphics techniques based on modelling raster surfaces, which often require high polygonal density to accurately represent smooth and irregular shapes [51, 62]. In computer-aided design (CAD) vectorial and piece-wise continuous entities, i.e. Non-Uniform Rational B-Spline (NURBS) patches, leverage similar polygonal subdivision schemes in a more compact and resolution-free parametrisation by representing the underlying geometry exactly [58, 59]. Nonetheless, most of the commercially available CAD tools exclusively focus on surface geometries and do not integrate parametric simulations or a solid finite-element analysis framework in the same vectorial domain. Solid and volumetric meshing is predominantly addressed in a raster fashion, where discrete polyhedral subdivision schemes fill with an unstructured plurality of solid elements the hollow space delimited by the superficial (closed) boundary [36]. In this case, conventional finite-elements methods ultimately approximate partial differential equations (PDEs) solutions over such discrete solid tessellations [61].

Isogeometric analysis (IGA) [22, 37] is a relatively recent computational approach that directly integrates finite-element analysis with vectorial NURBS-based geometries. By means of highly compact shape parametrisations, IGA has the advantage of high-performance and high-throughput continuous simulations while reducing geometrical approximation errors and providing higher numerical stability for the simulation solution profiles. Raster polygonal or polyhedral meshes, however, are not compatible with IGA. Conversely, a consistent NURBS-based geometrical domain is required to satisfy stringent conforming parametric conditions. The lack of a parametric framework to compactly trace solid shapes in IGA-compatible domains currently limited the development and application of Isogeometric Analysis to simple 2D/3D toy examples and few case studies.

With the aim of bridging the technological gap, this work first proposes a novel solid scaffolding framework jointly leveraging a topological, geometrical and parametric formulation. A solid scaffolding of minimal parameters and vectorial elements is sought to model the shape of the underlying structure by enforcing a conforming condition and preserving smoothness properties of a solid continuum, while optimising for the computational complexity of downstream simulations. The introduced scaffolding framework paves the way towards novel approaches to rationalising space for industrial design, CAD modelling, organic structures representation, and compact digital shape tracing with a particular focus on scalable, accurate and high-performance finite-elements analysis using IGA.

1.1 Related Work

NURBS Geometries. The pioneering work of [58, 59] first introduced a parametrisation framework to exactly represent 3D geometries with vectorial elements as opposed to raster finite-resolution meshes employed in polygonal modelling. Curvilinear and surface NURBS elements have de-facto become the standard for computed-aided design (CAD), manufacturing and engineering in a number of commercial and industrial applications. Beyond the established standards, the NURBS formulation generalises also for the parametrisation of higher-dimensional entities [18, 82]. Among those, solid NURBS build on extending and combining linear NURBS operators on univariate primitives, thus constituting a free-form cuboid in the most simple form. Recent research toolboxes [10, 24, 25, 38, 78] have developed a multi-platform formulation for high-dimensional vectorial representations, including hierarchical NURBS [11, 30] and IGA-compatible frameworks [8, 35] for the solution of PDEs based on splines. However, the design and construction of higher-dimensional geometrical domains has only been addressed for simple toy examples or individual case studies [22, 37].

Scaffolding Construction. The design and construction of geometrical partitioning domains was initially addressed in [54, 72, 73] with a scaffolding approach. In particular, a quadrilateral mesh is first introduced as the coarsest shape representation around a one-dimensional skeleton of high genus. Proof is provided for the existence of such coarse representation based on Voronoi diagrams and the problem of constructing an optimal scaffold is formalised as an integer linear program [73]. In these cases, affinities between the scaffolding and tensor product splines are mentioned, yet a structural subdivision and a parametric formulation specific for NURBS elements and their arrangement are not addressed. Also, strategies to recover the geometrical embedding of the underlying solid structure from the scaffolding are limited to coarse polygonal refinement schemes.
Shape Estimation. In [43] a solid meshing approach builds from a skeleton topology and integrates an adaptive refinement strategy to locally recover the shape of a structure delimited by a surface mesh. In a similar fashion, [44] proposed a hexahedral meshing method which optimises for cuboid elements leveraging a cascade of loop-wise cuts based on a surface-field aware block decomposition of a generic mesh. Alternative solid meshing techniques [28, 32, 46, 67, 76, 80] approximate the geometry of the tessellation by locally sampling the boundary of the structure and further subdivide the solid mesh in smaller polyhedra or finer inner partitions with adaptive or pre-defined resolution. Shape and curvature features as well as geometrical cues are often retrieved from the boundary mesh with directional fields [55, 60] and geodesic [23, 40, 50, 74] techniques, by first partitioning and segmenting superficial patches of the geometry and ultimately fitting the 3D coordinates of the solid polyhedral mesh. Dense solid meshes recover accurately the underlying geometry of the structure, often in detriment to a compact representation, where the resulting unorganised plurality of polyhedra exhibits a piece-wise linear and faceted lattice with pure positional continuity among neighbouring elements.

Smoothness and Continuity. A number of studies [17, 26, 47, 68] have proposed methods and strategies to recover a smoother lattice and higher degrees of continuity for associated limit surfaces focusing on polygonal meshes. In general, they build on refining first the mesh with a denser lattice and subsequently adjusting the coordinates of the geometry based on the local neighbourhood. In [70] a new class of subdivision surfaces is introduced by bridging the gap between polygonal meshes and uniform B-spline surfaces of arbitrary degree. In [69], an exact solution is provided for similar spline-based surfaces, and a closed form is devised for patches joining at extraordinary vertices of arbitrary valence. Irregular surface structures exactly recover the typically organic smoothness and higher degree of parametric continuity in their differential forms, which provided accurate simulation profiles for surface geometries using IGA [53]. Rectification routines and extended subdivisions are devised for convex polyhedral meshes [14, 45], where the coordinates of the inner lattice are constrained by the local connected neighbourhood. Yet, a solid smoothing strategy for higher degrees of continuity in a conforming solid NURBS scaffolding for IGA has not been investigated, and currently remains an open challenge.

IGA Applications. An increasing number of studies [7, 9, 12, 15, 22, 77] are investigating and employing finite-element analysis striving for a unified framework embedding vectorial geometries with continuous-domain accurate and fast simulations. Among those, the pioneering work by [7, 37] first introduced a CAD-compatible integration and a monolithic formulation of computational analyses with IGA, where spline-basis functions solve for linear elastic problems and (bio)-mechanical characterisations, as opposed to conventional polynomial finite-element methods [61]. In early medical applications, [9, 83] presented a subject-specific approach for tracing vessels with a set of conforming solid NURBS geometries. In a similar fashion, [10, 25, 38, 78] developed vectorial tools for modelling complex interactions between composite and multi-compartmental structures in a compact, general-purpose and light-weight manner. Quantitative IGA analyses proved higher accuracy and numerical stability [7] compared with conventional approaches, as the solution profile of PDEs eliminates the propagation of geometrical approximation errors. Most works, however, have focused on a limited set of geometries, addressing feasibility studies and proof-of-concept applications. This is mainly due to the lack of a principled scaffolding framework able to capture the underlying structure of more complex geometries and generalise for compatible real case scenarios on large scale [8, 77].

1.2 Outline

Aiming to tackle the aforementioned open problems in a unified manner, a conforming solid scaffolding for a generic 3D structure is described in the following sections. In section 2, a graph configuration is first considered as the underlying skeleton of the solid structure. In section 3, the generic form of a solid scaffolding is defined as a structured set of adjacent vectorial elements, and the conforming condition is introduced. In section 3.2 the luminal solid scaffolding construction is introduced, where the minimal number of vectorial elements, the associated spatial arrangement and the conforming parametric configurations are detailed. A straightforward extension, i.e. the wall scaffolding, is addressed in appendix A and alternative formulations are mentioned in appendix B. An interfacing configuration is introduced in section 3.2 for vectorial elements joining at a generic junction with arbitrary branching pattern. In section 4 the geometrical embedding of the scaffolding elements is described, including a data-driven fitting scheme. Lastly, in section 5, a smoothing paradigm is devised for the scaffolding, achieving higher degrees of geometrical and parametric continuity, as in an organic medium in the form of a continuum.
2 GRAPH CONFIGURATION OF THE STRUCTURE

A solid structure is often characterised by one or more branches, as elongated regions protruding from its main body. Complex structures may exhibit holes or concave regions, others have the form of laminar thin or thick shells. Convoluted and irregular organic structures, as well as composite CAD geometries, may show several of the above components, which can be locally decomposed in sub-blocks and modules [20, 48, 75, 81]. In any case, a graph can be determined as the skeleton underlying a branching portion of the structure by means of a number of (semi-)automatic computational routines and methods for different data types [63, 64]. Such graph embeds both spatial and topological configurations, where generally the nodes correspond to junctions or terminal end-points, and the edges correspond to the elongated connecting regions underlying each branch fig. 1.

3 CONFORMING SOLID SCAFFOLDING

The scaffolding builds on the graph configuration of the branching structure in section 2, as it subdivides each connecting branch in a pre-defined minimal number of vectorial elements. A rational partitioning of the structure’s space is introduced, and the scaffolding configures a set of conforming elements being jointly defined over high-dimensional, geometrical and parametric domains. In particular, the scaffolding comprises an organised and structured lattice of vectorial elements, each conforming to the neighbouring ones, and constitutes a conforming solid NURBS multi-patch fig. 2. The conforming condition is necessary for an IGA-compatible domain, and it represents the key parametric constraint and the structural criterion at the base of the solid scaffolding.

3.1 Vectorial Element

A vectorial element is the atomic component of the scaffolding and consists of a 3D free-form solid patch determined by NURBS primitives fig. 2. As introduced in [59], the vectorial element $H(u, v, w)$ is defined as a trivariate tensor product of NURBS curves along three independent parametric directions $(u, v, w)$, and has the form

$$H(u, v, w) = \sum_{i=1}^{l_u} \sum_{j=1}^{l_v} \sum_{k=1}^{l_w} R_{i,j,k}(u, v, w)P_{i,j,k},$$

with

$$R_{i,j,k}(u, v, w) = \sum_{i=1}^{l_u} \sum_{j=1}^{l_v} \sum_{k=1}^{l_w} N_{i,d_u}(u)N_{j,d_v}(v)N_{k,d_w}(w)w_{i,j,k},$$

where $R_{i,j,k}(u, v, w)$ are the rational basis functions; $P_{i,j,k} \in \mathbb{R}^3$ are the control points of cardinality $l_u, l_v,$ and $l_w$ in each independent parametric direction; $N_{i,d_u}(u)$, $N_{j,d_v}(v)$, and $N_{k,d_w}(w)$ are the univariate B-spline basis functions of degree $d_u$, $d_v$, and $d_w$ respectively defined on the three independent parametric directions; and $w_{i,j,k}$ are the strictly positive weights of the rational basis functions. The span of the basis functions’ parametric domain is sampled in each independent direction by a set of intervals defined by the knot vectors $k_u$, $k_v$ and $k_w$ respectively. The generic knot vector $k$ comprises a set of real-valued knots $k_1, ..., k_r \in [0, 1]$ and is defined as

$$k = \{ k_1, \ldots, k_1, k_2, \ldots, k_r \}, \quad \text{with} \quad r = l + d + 1.$$
Solid NURBS Conforming Scaffolding for Isogeometric Analysis

Fig. 2. Solid Scaffolding of a Torus: (a) Minimal element, (b) Equivalent multi-patch (4 elements) with reflection lines; (c) Multi-patch explosion view; (d) Individual element: control points lattice and inner solid sectioning; (e) Parametric embedding: individual element isomorphic to a cube; (f) Multi-patch sides (edges) facing (along) directions \((u, v, w)\), respectively: dark/light red for \(u = \{0, 1\}\), dark/light green for \(v = \{0, 1\}\), and dark/light blue for \(w = \{0, 1\}\) - conforming interfaces facing \(w\); boundaries facing \(u\) and \(v\).

The knot vector is assumed open, i.e. \(k_1 = 0, k_r = 1\) and the multiplicity \(m = d + 1\), with \(r\) being the total cardinality of the knots, \(l\) being the number of control points in the generic parametric direction, and \(d\) being the arbitrary degree of the associated univariate B-spline basis function.

The parametrisation in eq. (1) maps a solid tensor grid defined on the parametric domain to a physical-space, where each vectorial element represents a solid free-form cuboid. The free-form shape is modulated by the 3D coordinates of the control points \(P_{i,j,k}\) and by the weights \(w_{i,j,k}\) of the rational basis functions. The boundary of the element comprises 6 sides of quadrilateral profile, which are oriented, in opposite pairs, to face the directions of the parametric domain.

3.1.1 Conforming Condition. A pair of vectorial elements is said to be adjacent when there is at least one side in common for each element. Such shared (or adjacent) sides are referred as interfaces, whereas the free-end unshared sides are referred as boundaries. The same pair of adjacent elements is also said to be conforming when all the interfaces are conforming, i.e. the parametrisation of each pair of adjacent sides is matching. In other words, for each interface, all the control points, as well as, all the knot vectors and all the weights of the rational basis functions and the degrees of the associated univariate B-spline basis functions defining the sides of the adjacent sides must coincide, up to a different orientation of the elements in the parametric domain.

A conforming solid scaffolding requires all adjacent elements in the lattice jointly meet the conforming condition.

3.2 Luminal Scaffolding Construction

A luminal scaffolding builds on the branching structure graph in section 2, where higher density of branches and greater complexity of the branching pattern require an increasing number of elements to minimally parametrise the underlying spatial regions. The luminal scaffolding comprises the organised set of vectorial elements filling the innermost space of a branching structure, e.g. the fluid region.
Fig. 3. Luminal Scaffolding Construction from Graph: (a) Bifurcation; (b) 5-way-junction: 4 elements required per branch; (c) Cross-sectional quadrants arrangement and elements adjacency per branch - note the conforming interfaces of adjacent elements couple pairs of sides facing \( u \) and \( v \); (d) Scaffolding construction for a 3D mesh structure (Fertility) with multiple junctions and elongated portions. For simplicity, all scaffolding elements are shown as piece-wise linear segments.

Fig. 4. Quadrilateral junction simplex: (a) Set of incident directions \( \hat{n}^{(n)} \) of a generic \( n \)-way-junction, here \( n = 5 \). (b) Associated atomic simplex \( Q_{\text{atom}} \) from three clustered principal directions: white nodes (original extraordinary vertices in black), colour-coded quadrant arcs surrounding the initial directional partition with a quadrilateral profile. (c) Resulting simplex \( Q \) after \( n-3 \) iterative bisections: new extraordinary vertices in white. (d) Quadrilateral and quadrant-based interfaces all facing \( w \) constructed on \( Q \).

as in a set of tubes or connected chambers, or the volumetric space occupied by a solid object. Leveraging the free-form shape of each element, the luminal scaffolding models the branching structure as a set of connecting portions that elongate for each structure protrusion encoded in the graph (fig. 3).

**Minimal Elements.** The scaffolding subdivides the branching structure in a pre-defined number of vectorial elements based on the topology of the graph. In general, the luminal scaffolding requires 4 vectorial elements per branch, assuming branches arbitrarily connect with generic \( n \)-way-junctions (fig. 3).

**Arrangement and Adjacency.** For a generic graph with arbitrary branching pattern, the luminal scaffolding arranges each branch in 4 organised cross-sectional quadrants, each accounting for an individual element. This results in 4 adjacent vectorial elements elongated along the longitudinal direction of the branch, either joining a junction with a terminal endpoint, alternatively connecting two junctions. Assuming the parametric direction \( w \) mapping the longitudinal direction along the branch, each element is adjacent to other two elements of the same branch along one of its cross-sectional sides. In particular, two interfaces are determined for each vectorial element in the correspondence of the interior part of the quadrant: one interface facing \( u \) and the other interface facing \( v \) respectively (dark red for \( u \) and light green for \( v \) in fig. 5). The remaining pair of sides, i.e. the boundaries, determines the exterior part of the quadrant: respectively, one boundary side facing \( u \) (light red side) and another boundary side facing \( v \) (dark green side), opposite to the interfaces. The boundaries define a pseudo-circumferential profile relative to the elongation of the branch.

At any terminal branch, each element of the scaffolding terminates with a boundary side facing the longitudinal direction \( w \). At junctions, each element determines an interface with another adjacent element of a neighbouring incident branch. The scaffolding configuration at the junction interfaces is defined by a quadrilateral junction simplex.
Quadrilateral Junction Simplex. In a generic junction, all the elements of each incident branch adjacently meet in the neighbourhood of the junction node. This determines a structured set of interfaces, all facing the w parametric direction, where each interface (as any other side) of the elements are configured with a quadrilateral profile.

These structural requirements are met by introducing the quadrilateral junction simplex $Q$ (fig. 4). The simplex is a rational partitioning of the junction’s space and determines an interfacing scaffolding configuration, whose atomic form underlies a bifurcation.

The topology of the atomic simplex $Q_{\text{atom}}$ accounts for a total of 5 nodes and 6 edges being configured in 3 loops, each comprising 4 nodes and 4 edges, which are jointly connected by 2 common nodes, i.e. the initial extraordinary vertices of the atomic simplex. The associated spatial embedding of the atomic simplex delimits the interfacing cross-sectional areas of three incident branches, where each loop of $Q_{\text{atom}}$ surrounds the incidental direction of the branch with 4 connecting arcs. In this form, each loop defines a quadrilateral profile, and each arc of each loop underlies a quadrant.

The geometrical embedding of an atomic simplex is formulated by considering the directions of the incident branches as three non-coincident unit vectors $\hat{v}_i \in \mathbb{R}^3$, with $i = \{1, 2, 3\}$, centred at the origin of a local reference system. The initial extraordinary vertices lie along a common axis in opposite directions, where the common axis $\hat{v}$ is defined as

$$\hat{v} = \frac{\sum_{i=1}^{3} \hat{v}_i \times \hat{v}_j}{|\sum_{i=1}^{3} \hat{v}_i \times \hat{v}_j|}.$$  \hspace{1cm} (4)

The unit vector $\hat{v}$ is determined as the average of the cross-products of the incidental directions considered in pairs, in circular shift, i.e. $j = i \pmod{3} + 1$. The remaining three independent nodes of the atomic simplex $Q_{\text{atom}}$ lie along the intermediate directions $\hat{v}_{i, j}$, which are orthogonal to the common axis $\hat{v}$. The intermediate directions are defined as

$$\hat{v}_{i, j} = f_{i, j} \frac{\hat{v}_i \times (\hat{v}_j \times \hat{v}_k)}{|\hat{v}_i \times (\hat{v}_j \times \hat{v}_k)|}, \quad \text{with} \quad \hat{v}_{i, j} = \frac{\hat{v}_i \hat{v}_j}{|\hat{v}_i \hat{v}_j|},$$  \hspace{1cm} (5)

being $\hat{v}_{i, j}$ the bisecting unit vector between each pair of incident directions. The flip factor $f_{i, j}$ determines whether the associated intermediate direction are considered in opposite sign. This avoids inconsistent partitions of the space for particularly close and narrow sets of incidental directions. Each flip factor $f_{i, j}$ is defined as

$$f_{i, j} = \begin{cases} -1 & \text{when} \ p_{i, j} > 0 \land p_{j, k} \leq 0 \land p_{k, i} \leq 0, \vphantom{\frac{|\hat{v}_i \times (\hat{v}_j \times \hat{v}_k)|}{|\hat{v}_i \times (\hat{v}_j \times \hat{v}_k)|}} \\ 1 & \text{otherwise} \end{cases}, \quad \text{where} \quad p_{i, j} = \hat{v}_{i, j} \cdot \hat{v}_k,$$  \hspace{1cm} (6)

and

$$\hat{v}_{i, j} = \frac{\hat{v}_i \times (\hat{v}_j \times \hat{v}_k)}{|\hat{v}_i \times (\hat{v}_j \times \hat{v}_k)|}.$$  \hspace{1cm} (7)

The projection $p_{i, j}$ is computed as scalar-product between the bisecting unit vector $\hat{v}_{i, j}$ and $\hat{v}_k$, being the latter the unit vector associated to the $k$-th incidental direction and orthogonal to the common axis $\hat{v}$, with $k = (i + 1 \pmod{3}) + 1$.

In the general form, the quadrilateral junction simplex $Q$ of a junction with $n$ incident branches topologically consists in an adjacent stack of atomic simplexes, where each pair mutually shares a common loop.

In a physical-space embedding, such topological composition is equivalent to a cascade of spatial bisections of an initial atomic simplex, which first considers three principal incidental directions clustered from the $n$-way-junction (fig. 4). In this case, the total number of required bisections equals to $n - 3$, for $n$ incident branches. At each bisection, the initial parent loop is split into a pair of child loops following a binary spatial partition by connecting any alternating pair of vertices of the parent loop with an arc, and by splitting the connecting arc at the midpoint. This binary spatial partition is iterated for the newly generated child loops until convergence, where each child loop surrounds every incidental direction of the $n$-way-junction. At convergence, each loop of the simplex inherits a quadrilateral profile.

The resulting spatial configuration of $Q$ is data-driven and is determined upon the incidental directions and sizes of the branches at the junction. Each bisection is based on maximising the volumetric partition for each incident branch.

A set of interfacing quadrants is obtained for each loop in $Q$, by first connecting all the vertices of the simplex with its centroid, then by splitting each arc of each loop at the midpoint (fig. 4). This determines a consistent quadrant-based configuration and an initial geometrical embedding of the incident elements. In particular, for each interface facing $w$, the subset of vertices belonging to the quadrant-based simplex coincides with the a subset of control points in eq. (1).
4 GEOMETRICAL EMBEDDING

The conforming scaffolding associates a 3D geometrical embedding to the lattice of control points in eq. (1). Each free-form element of the scaffolding recovers both shape and size of the underlying portion of the structure, similarly to [41]. The directional formulation of the interfacing quadrilateral junction simplex in section 3.2 provides an initial directional embedding, whereas the geometrical extent and configuration of each branch of the scaffolding is detailed in the following sections, by viable fitting strategies for different input data.

4.1 Curvilinear Primitives and Lattice

The geometrical embedding of each vectorial element is determined by a solid profiling operator. This is controlled by a cross-sectional quadrilateral loop of varying shape sweeping along the branch-wise skeletal curvilinear primitive. In particular, the quadrant cross-sectional quadrilateral loop comprises the curvilinear profiles at the interfacing simplexes and the outlines estimated from the superficial boundary of the structure and the underlying skeleton, at the extremities and along each branch, respectively. Internal control points of the solid lattice are derived with a composition of blended interpolations from such curvilinear primitives [59].

4.1.1 Skeletal Primitives. The underlying skeletal centerline of the $i$-th branch is parametrised as a NURBS curve $C_{\text{skeI}}(w)$, conforming to the univariate formulation in eq. (1) along the longitudinal direction $w$. The control points and the associated knot vector are estimated following [49, 52, 59], considering an adaptive sampling scheme accounting for uniform-, or non-uniform and curvature-preserving samples, up to a desired spatial resolution (fig. 5). The curvilinear primitive $C_{\text{skeI}}(w)$ links either a pair of junctions, or a junction with a terminal node, and each point of $C_{\text{skeI}}(w)$ is associated with a set of orthogonal bases, comprising a tangential unit vector $\hat{t}_i$ and a pair of normal $\hat{e}_i$ and binormal $\hat{f}_i$ unit vectors, as in a Frenet–Serret apparatus [33]. Both normal and binormal bases along the skeletal primitive determine the directional embedding of the branch-wise scaffolding quadrants.

At a junction simplex $Q$, the normal $\hat{e}_i$ and binormal $\hat{f}_i$ unit vectors are defined for the $i$-th branch as

$$\hat{e}_i = \frac{\tilde{k}_x \tilde{k}_y}{|\tilde{k}_x \tilde{k}_y|} \quad \text{and} \quad \hat{f}_i = \frac{\tilde{l}_x \tilde{l}_y}{|\tilde{l}_x \tilde{l}_y|} \quad \text{with}$$

$$\tilde{k}_i = \frac{\tilde{k}_x (\tilde{k}_x \tilde{y}_i) \tilde{y}_i - \tilde{k}_y (\tilde{k}_y \tilde{y}_i) \tilde{x}_i}{|\tilde{k}_x (\tilde{k}_x \tilde{y}_i) \tilde{y}_i - \tilde{k}_y (\tilde{k}_y \tilde{y}_i) \tilde{x}_i|} \quad \text{and}$$

$$\tilde{l}_i = \frac{\tilde{l}_x (\tilde{l}_x \tilde{y}_i) \tilde{y}_i - \tilde{l}_y (\tilde{l}_y \tilde{y}_i) \tilde{x}_i}{|\tilde{l}_x (\tilde{l}_x \tilde{y}_i) \tilde{y}_i - \tilde{l}_y (\tilde{l}_y \tilde{y}_i) \tilde{x}_i|}$$

Conforming Constraints. The conforming condition of the considered scaffolding introduces a certain dependency among the parameters of each vectorial element in the lattice. In line with the construction, the parametric components along $w$ and $u$ directions are equivalent, i.e. the the univariate basis functions degrees $d_u = d_w$ in eq. (2), as well as, the knot vectors $k_w = k_u$, and the cardinality of control points $l_w = l_u$ as in eq. (1) and eq. (2), respectively for each vectorial element. Geometrically, the control points coordinates associated to each adjacent side of any pair of conforming vectorial elements coincide as well. Each element of the luminal scaffolding has independent parametric components along $w$, i.e. arbitrary degree $d_w$, arbitrary spacing of the knot vector $k_w$ and arbitrary cardinality of control points $l_w$.

Fig. 5. Curvilinear primitive: (a) Skeletal curve $C_{\text{skeI}}(w)$: curvature-preserving (magenta) and uniformly spaced (cyan) samples, with terminal orthogonal bases; (b) Normal $\hat{e}$ (orange) and binormal $\hat{f}$ (purple) vectors matching the terminal quadrant bases for $\theta$; (c) Minimal torsion scaffolding and control points; (d) Scaffolding between two junctions (Phantom) matching the quadrant bases for $\theta$. 

Phantom
where, $\hat{x}_1$ and $\hat{y}_1$ are the unit vectors orthogonal to the tangential $\hat{n}_i$, respectively joining the local pair of extraordinary vertices of the quadrilateral loop and the opposite pair of loop’s midpoints. The normal and binormal bases of a terminal node follow the Frenet–Serret formulas \[33\] starting from the bases at the junction simplex as in eq. (8), and osculate with minimal intrinsic torsion.

By directly matching the the normal and binormal bases of two connected junctions, the parametrisation of the $i$-th branch results in an additive structural twist. To reduce such structural twist, the bases are quadrant-wise matched by minimising a torsional angle and by diluting it along the skeletal primitive (fig. 5).

Assuming $\mathbf{n}_i(a), \mathbf{e}_i(a), \mathbf{f}_i(a)$ and $\mathbf{n}_i(b), \mathbf{e}_i(b), \mathbf{f}_i(b)$ being the orthogonal bases at the endpoints of $C_{dei}(w)$ underlying the $i$-th connecting branch, at the corresponding junctions $a$ and $b$, the torsional angle $\theta$ is given by

$$\theta = \min \left\{ \arccos \left( \hat{e}_i^{(a)\perp} \cdot \left( R_{\mathbf{n}_i(b)} \left( \frac{j \pi}{2} \right) \hat{e}_i^{(b)} \right) \right), \text{ for } j = 0, 1, 2, 3 \right\}, \tag{10}$$

where $\hat{e}_i^{(a)\perp}$ is the orthogonal projection of $\hat{e}_i^{(a)}$ on $\hat{\mathbf{n}}_i^{(b)}$, and the rotation matrix $R_{\mathbf{n}_i(b)}(\frac{j \pi}{2})$ accounts for quadrant rotations of the bases $\hat{e}_i^{(b)}, \hat{f}_i^{(b)}$ around $\hat{\mathbf{n}}_i^{(b)}$.

Leveraging the symmetry of the branch-wise quadrants, the maximal structural torsion along the skeletal primitive corresponds to $\theta_{\text{max}} = \frac{2 \pi}{3}$.

4.1.2 Cross-Sectional Quadrilateral Loops. The projected image of a junction simplex $Q$ on the superficial boundary of the structure determines the curvilinear profiles of the cross-sectional quadrilateral loops in each respective quadrant. In particular, each pair of extraordinary vertices and loops’ midpoints of $Q$ is first mapped following the directional formulation in section 3.2. Then, each arc of the simplex loops is delineated with geodesics \[23, 40, 50, 74\].

The parametrisation of each geodesic arc is constrained by the conforming conditions along the parametric directions $u$ and $v$. For a luminal scaffolding, each geodesic arc of a quadrant is first split in two segments at the midpoint, and each segment is parametrised along $u$ and $v$ respectively, in an alternating and opposite scheme (fig. 6). This determines a pair of associated curvilinear primitives $C_1(u)$ and $C_1(v)$ for each arc of the quadrant, following the pseudo-circumferential arrangement as in section 3.2. The inner part comprises pairs of curvilinear primitives along $u$ and $v$ fitting the segments connecting each pair of extraordinary vertices and each pair of loop’s midpoints to the junction node itself. This determines another pair of curvilinear primitives, namely $C_0(u)$ and $C_0(v)$, originating from the junction node, each underlying a pseudo-radial direction. For each quadrant, the 4-tuple of curvilinear primitives $C_0(u), C_0(v), C_1(u)$ and $C_1(v)$ constitute the sides of a quadrilateral loop on $(u, v)$ as in fig. 6.

In a similar manner, cross-sectional quadrilateral loops are determined for the elongation of each branch (fig. 6), where consecutive 4-tuple of curvilinear primitives are sampled orthogonal to the longitudinal direction $w$. Seam-cuts conforming to the skeletal primitive $C_{dei}(w)$ connect the projected images of the simplexes along the branch as in the underlying graph (fig. 6). At the outer part of the quadrant along the branch, similar curvilinear geodesic arcs are determined by leveraging a linear combination of the normal $\hat{x}_1$ and $\hat{y}_1$.
Fig. 7. Geodesic Fitting – Gallery of Polygonal Surface Meshes: mapping the geometrical embedding of the scaffolding in quad-based segmentation seam-cuts. Junction simplexes and terminal nodes: (gold), elongated branches (cerulean) and sampling outlines (lilac).

binormal $\hat{f}_i$ directions along $C_{skel}(w)$. The orthogonal bases are (non-)linearly mapped onto the superficial boundary of the structure, and the associated projections constrain the local geodesics outlines delineation.

4.1.3 Internal lattice. The internal lattice of each quadrant, and of each vectorial element, is determined with a composition of blended interpolations from the cross-sectional quadrilateral loops along the skeletal primitive. In particular, each 4-tuple of curvilinear primitives $C_0(u), C_0(v), C_1(u)$ and $C_1(v)$ encloses a bilinearly blended Coons patch [27], whose conforming parametrisation on $(u, v)$ accounts for the interpolated inner control points coordinates of the lattice (fig. 6). The conforming parametrisation of the internal lattice is given by orderly stacking and further interpolating the cross-sectional Coons patches along $C_{skel}(w)$, with a profiling operator as in [58, 59].

4.2 Geodesic Fitting Strategies

Curvilinear arcs are determined using geodesics by connecting two end-points on the superficial boundary of the branching structure. Fitting and parametrising the curvilinear primitives follows [49, 52, 59], in keeping with the conforming constraints.

Polygonal Surface Meshes. Superficial outlines underlie pseudo-circumferential and longitudinal profiles along each branch. Geodesic curves are extracted with state-of-the-art methods as in [23, 74] leveraging exact or approximated level-sets on a tessellated polygonal mesh. The directional embedding of the scaffolding is first projected on the polygonal surface mesh by means of a non-linear inverse skteleton-to-mesh mapping as in [3], or by semi-automatic user adjustments. The projected images of each junction simplex nodes constitute the geodesic end-points. Along each branch, the orthogonal bases of the Frenet–Serret apparatus elicit preferential diffusion directions on the mesh, which constrain the geodesics along directional fields [55, 60] in quad-regularised segmentation seam-cuts and outlines (fig. 7).

Volumetric Imaging. Geodesic active contours [19], i.e. snakes, delineate the superficial boundary of a structure from 3D volumetric imaging. In particular, snakes contour pseudo-circumferential profiles along the longitudinal axis of each branch (fig. 8). The volumetric image is first cross-sectionally resampled with a series of curve-to-planar projections [39] forming a branch-wise stack of slices orthogonal to the centerline. Snakes evolve on each slice minimising a level-set potential [65, 66] in the correspondence of the boundary of the structure. For the elongation of the branch, the directional embedding of the scaffolding is linearly projected onto the snakes coordinates, directly fitting the curvilinear arcs (fig. 8). At the junctions, the directional embedding of the simplexes fits a 3D point-cloud determined by the overlapping snakes with least-squares (fig. 8).
5 SMOOTHING PARADIGM

The parametric and geometrical continuity of each scaffolding element depends on the degrees of the basis functions and on the multiplicity of each knot in the associated knot vector. In particular, referring to eq. (3) and considering a generic parametric direction of a vectorial element, the number of continuous derivatives at the knot \( k \) equals to \( d - m(k) \), with \( d \) and \( m(k) \) being the univariate B-spline degree and the multiplicity of the knot \( k \), respectively.

Considering open knot vectors as in eq. (3), the parametric and geometrical continuity of any pair of conforming elements of the scaffolding is only positional, i.e. the conforming elements are mutually \( G^0 \).

This may result in discontinuous curvature, geometrical creases and visible sharp edges, as well as in differential discontinuities of computational simulation profiles at the contiguous boundaries and across interfaces of the scaffolding. Similarly to isoparametric Hermite elements [56], a solid smoothing paradigm is devised for the scaffolding, achieving higher smoothness and continuity, typical of an organic structure as a continuum.

The solid smoothing paradigm first builds on a topological subdivision of the scaffolding control points into a set of nested sub-lattices, i.e. medial shells. Then, the geometrical embedding of each sub-lattice is adjusted with a smoothing scheme leveraging concepts from state-of-the-art smoothing algorithms employed in subdivision surface modelling.

5.1 Medial Shells Subdivision

A topological subdivision of the scaffolding control points determines a set of nested sub-lattices at different depths, i.e. a set of medial shells (figs. 9 and 10). A medial shell \( M \) is a lattice graph of regular tiling, comprising a subset of control points \( P \) and a subset of edges \( E \) connecting points of the same shell in quadrilateral cells. Such medial shell can also be regarded as a quadrilateral (open or closed) mesh. A set of medial shells (fig. 9) can be defined over the structured lattice of control points in an individual element as

\[
M_\tau = \{(P, E)|P = \{P_{i,j,k} | t_{i,j,k} = \tau \}, E = N_6(P)\}, \quad \tau = 0, 1, \ldots, \bar{\tau}.
\]

(11)

The scalar value \( t_{i,j,k} \in \mathbb{N} \) is the depth tag of each control point \( P_{i,j,k} \) in the structured lattice. All control points with same depth tag \( t_{i,j,k} = \tau \) constitute the vertices of the associated medial shell \( M_\tau \), and the respective edges are defined by the 6-connected neighbourhood \( N_6 \) pattern, as in the original structured lattice of the element. The depth-wise medial shell subdivision follows a recursive definition of the tag \( t_{i,j,k} \), all tags are first initialised as infinite values for the entirety of the structured lattice, whereas 0 values are imposed for the boundary sides. A recursive scheme assigns a finite value to each tag in the lattice as

\[
t_{i,j,k} = \min \{ t_{i,j,k} , \min \{ t_{N_6(i,j,k)} \} + 1 \}.
\]

(12)
where $\mathbf{t}_{N_{26}(i,j,k)}$ is the array of tag values associated to the 26-connected neighbourhood $N_{26}$ relative to the index tuple $(i,j,k)$ in the structured lattice of each (multi-patch) element.

Multiple nested shells are generated from the superficial boundary of the lattice, i.e. at null depth, following an iterative integer-step shrinking of the exterior shell towards the innermost region of the structure. In particular, each inner shell represents a discrete contraction of the relative outer shell, up to an ultimate irreducible shell $M_{\tilde{\tau}}$, i.e. the medial locus, which lies in the neighbourhood of the structure skeleton and can be a degenerate lattice graph.

### 5.2 Medial Shells Smoothing

Given the analogy between medial shells and quadrilateral meshes, the smoothing paradigm leverages concepts introduced by state-of-the-art subdivision surface algorithms [17, 70]. Reference literature generally employs first a local refinement of the mesh with local subdivisions. Then, vertices coordinates are adjusted according to a smoothing scheme based on the vertex valence $\nu$, i.e. the number of edges that meet at each vertex. In a similar manner, a lattice refinement by knot-insertion can be alternated to the following smoothing paradigm at each smoothing step, reaching the underlying limit geometry (fig. 13).

#### 5.2.1 Medial Shell Fringe

The smoothing paradigm operates on each medial shell fringe $\mathcal{F}$ of the (sub-)lattice(s). The fringe is defined as the union of the boundary rims of a lattice within a certain outskirt of influence. By way of example, the outermost and
minimal-influence fringe of a solid scaffolding coincides with the set of edges belonging to the boundary sides of each vectorial element.

Considering the topological subdivision in section 5.1, the definition of a shell-wise fringe $F_{(M_\tau)}$ is applied to each contracted medial shell, in keeping with the parametric arrangement of the scaffolding elements. In detail, the medial shell fringe $F_{(M_\tau)}$ includes the vertices belonging to the boundaries rims of the contracted sub-lattice. These are labelled either as corner-, or edge-lattice vertices (or face-lattice vertices, with increasing outskirt of influence). Additional vertices at the rims of the scaffolding interfaces are also included in the shell-wise fringe $F_{(M_\tau)}$, these all being labelled as edge-lattice vertices for a minimal outskirt of influence, or labelled as face-lattice vertices when they are corners of the respective individual adjacent elements. Note that all the extraordinary vertices of a simplex $Q$ in section 3.2 coincide with face-lattice vertices of the fringe.

Smoothing Scheme. The smoothing scheme determines a geometric dual configuration for the vertices in each fringe $F_{(M_\tau)}$. Similarly to [70], in the simplest form, the smoothing scheme adjusts the coordinates of each vertex by adopting an iterative weighting scheme based on the vertex valence $\nu$ and on the label of the vertex.

For each corner- or face-lattice vertex (fig. 11), the geometrical coordinates are iteratively adjusted as

$$P_{i+1} = \alpha(\nu)P_i + \sum_\nu \beta(\nu)P_{i_{\nu}}^{(e)} + \sum_\nu \gamma(\nu)P_{i_{\nu}}^{(f)}$$,

(13)

where $P_i$ represents the coordinates of the considered corner- or face-lattice vertex of the fringe $F_{(M_\tau)}$, $P_{i_{\nu}}^{(e)}$ represents the coordinates of the respective $\nu$-th edge-wise connected neighbour in $M_\tau$, and $P_{i_{\nu}}^{(f)}$ represents the coordinates of the respective $\nu$-th face-wise connected neighbour in $M_\tau$, respectively at the $i$-th iteration. The weights are defined by the valence $\nu$ of the fringe vertex as

$$\alpha(\nu) = \frac{\nu-3}{\nu}, \quad \beta(\nu) = \frac{2}{\nu^2}, \quad \gamma(\nu) = \frac{1}{\nu^2}$$,

(14)

and satisfy an affine invariant scheme, i.e. $\alpha(\nu) + \nu \beta(\nu) + \nu \gamma(\nu) = 1$.

In this case, corner-lattice vertices of the fringe usually have valence $\nu = 3$, whereas face-lattice vertices of the fringe are associated either to regular vertices ($\nu = 4$), or to extraordinary vertices with arbitrary valence $\nu > 4$. 

---

Fig. 11. Closed Medial Shell Fringe – Multi-patch 3-way-junction: (a) Parametric embedding and exterior shell fringe - selected vertices (magenta outlines); (b) Neighbourhoods of corner-lattice vertices (○): edge-connected neighbours (green), face-connected neighbours (blue); (c) Neighbourhoods of face-lattice vertices (□): edge-connected neighbours (green) and face-connected neighbours (blue). (d) Neighbourhoods of edge-lattice vertices (△): edge-connected neighbours as in eq. (15) (green).
Conversely, for each edge-lattice vertex (fig. 11), the geometrical coordinates are iteratively adjusted as

\[ P_{i+1} = \tilde{\alpha} P_i + \sum_{\nu} \tilde{\beta}_\nu P_{i_{\parallel \nu}}, \tag{15} \]

where, at the \( i \)-th iteration, \( P_i \) represents the coordinates of the considered edge-lattice vertex of the fringe \( F(M_{\tau}) \), and \( P_{i_{\parallel \nu}} \) represents the coordinates of the \( \nu \)-th edge-wise connected neighbour in \( M_{\tau} \), whose parametric direction in the (sub-)lattice lies perpendicularly to the one of the considered fringe vertex. In other words, each edge-wise connected neighbour in \( M_{\tau} \) belonging to the same rim in the (sub-)lattice is excluded. The latter condition imposes each edge-lattice vertex of the fringe has valence \( \nu = 2 \). The weights, in this case, are fixed as \( \tilde{\alpha} = \frac{1}{2} \) and \( \tilde{\beta} = \frac{1}{4} \).

The iterative smoothing scheme ultimately converges for a machine error evaluated on the norm \( |P_{i+1} - P_i| \).

**Smoothing Scheme of Open Medial Shells.** Certain configurations of the medial shells result in vertices of the fringe \( F(M_{\tau}) \) having an open-fan in the quadrilateral tiling. In this particular case, the smoothing scheme of the corner-, edge- and face-lattice vertices belonging to the open-fan changes to account for the open boundary of the lattice.

Each edge-lattice vertex of the open-fan is kept unaltered, whereas each corner- and face-lattice vertex of the open-fan is treated as a particular edge-lattice vertex of \( M_{\tau} \) (fig. 12), and the geometrical coordinates are iteratively adjusted as

\[ P_{i+1} = \bar{\alpha} P_i + \sum_{\nu} \bar{\beta}_\nu P_{i_{\perp \nu}}, \tag{16} \]

Here, \( P_{i_{\perp \nu}} \) represents the coordinates of the \( \nu \)-th edge-wise connected neighbour in the open-fan of \( M_{\tau} \). As in eq. (15), the resulting valence is \( \nu = 2 \), and the weights coincide to \( \bar{\alpha} = \frac{1}{2} \) and \( \bar{\beta} = \frac{1}{4} \).

**Smoothing Scheme of the Medial Locus.** The medial locus \( M_{\tilde{\tau}} \) makes exception in the smoothing scheme, as the fringe of a degenerate lattice graph may not be defined. For each vertex of the medial locus, the original edge-wise 6-connected neighbourhood \( (N_6) \) of the conforming lattice is considered, regardless of the medial shell of belonging. The associated geometrical coordinates are iteratively adjusted as

\[ P_{i+1} = \tilde{\alpha} P_i + \sum_{\nu} \tilde{\beta}(\nu) P_{i_{N_6}}, \tag{17} \]
Solid NURBS Conforming Scaffolding for Isogeometric Analysis

Fig. 13. Solid Smoothing Paradigm at Convergence: (a) Single cuboid; (b) Multi-patch 4-way-junction with locally mixed open and closed medial shells. Resulting geometry, depth-wise medial shells of control points, reflection lines and inner solid trabecular view.

where, at the \(i\)-th iteration, \(P_i\) represents the coordinates of the considered vertex of the medial locus \(M_i\), and \(P_i^{(\nu)}\) represents the coordinates of the \(\nu\)-th edge-wise connected neighbour in \(N_i\) of the conforming lattice. The weights are defined as \(\bar{\alpha} = \frac{1}{2}\) and \(\bar{\beta}(\nu) = \frac{1}{2\nu}\), satisfying an affine invariant scheme.

Open-fan vertices of the medial locus \((\nu < 6)\) are adjusted by considering only the neighbours in \(N_i\) belonging to the same boundary side of the conforming scaffolding.

6 RESULTS

Input Data. A set of synthetic and CAD geometries with varying shape, complexity, composite graph structure and branching patterns were obtained by construction. Popular benchmarking geometries used in computer graphics applications have been considered form [2, 84] as reference surface meshes for the scaffolding parametrisation. Also, representative multi-modal scans, i.e. computed tomography (CT) and magnetic resonance (MR), from available medical repositories [13, 57] were considered for tracing anatomical structures from raster volumetric imaging.

Parametric and Implementation Details. All parametrisations are considered for solid vectorial elements of cubic degree, i.e. \(d_u = d_v = d_w = 3\), with unitary weights of the rational basis functions. Minimal number of control points \(l_u, l_v, l_w \geq 4\) are adopted by enforcing an adaptive spatial resolution, based on [52]. For simplicity, and in keeping with the conforming constraints, the parametrisations along \(u\) and \(v\) directions in the luminal scaffolding employed either uniformly-spaced, or non-uniformly symmetrically-spaced knot vectors \((k_u, k_v)\). The technical implementation of the introduced scaffolding framework builds on available tools from [10, 25, 78].

Parametrisation Evaluation. Features of the parametrised structures account for the total number of scaffolding elements, the density of control points lattice, the computational time, and the accuracy for fitted geometries.

For synthetic and CAD structures, the compactness of the proposed approach is first evaluated by comparing our parametrisation with state-of-the-art solid meshing techniques employed in computational simulations. For each structure, an optimal tetrahedral mesh is generated using [67], reporting the number of quadratic-element tetrahedra, total number of vertices and computational time.
Similarly, the scaffolding parametrisation is evaluated for polygonal meshes. The fitting accuracy of the geometric embedding is reported considering the input surface mesh as reference. High accuracy corresponds to minimal deviation from the reference mesh, in particular, the accuracy is evaluated as the complement of the percentage parametrisation error, i.e. \( \text{Acc.} = (1 - \varepsilon) \cdot 100\% \), and the error \( \varepsilon \) is computed as the Euclidean (or Hausdorff: \( \varepsilon_{95} \)) distance between the closest points on the boundary surface of the parametrised structure and on the reference surface using [1], normalised by the local radius of the underlying inscribed sphere [71].

For representative structures, the proposed parametrisation is also compared against the state-of-the-art linear-elements hexahedral meshing method [44].

The parametric accuracy of fitted anatomical structures is evaluated on the normalised distance between the closest points on the parametrised boundary surface and the sampled geodesic active contours as reference. A qualitative comparison with seminal work by [77, 83] is also provided.

6.1 Synthetic and CAD Geometries

Simple to complex shapes are modelled using the introduced scaffolding. More complex geometries combine a composition of interfacing luminal and wall scaffolds to model holes and complementary regions, leveraging modular and local blocks decomposition. Individual elements are assessed in the explosion view (fig. 14), where minimal multi-patches exactly recover the geometrical shape of large and complex geometries. Smooth and sharp features of the structures are preserved by enforcing arbitrary smoothing configurations to the medial shells. The continuum structure of the parametrised solids is shown in the trabecular view (fig. 14), where free-form cuboid cells are sampled from the vectorial domain. The compactness of the proposed solid parametrisation accounts for dozens to hundreds of cubic-degree elements, comprising few thousands of control points in the solid lattice for increasing structure complexity (table 1). The compactness is compared against adaptive quadratic-element tetrahedral meshing methods employed in computational simulations [67].

To accurately represent the same structure, tetrahedral meshes required a dense tessellation of elements and vertices, which differs by several orders of magnitude compared to the proposed parametrisation. Coarser tessellations are feasible (fig. 15), yet higher deviation from the boundary structure is observed, introducing larger geometrical errors and approximations for computational simulations. The structures parametrised with our approach exhibit higher degree of smoothness and parametric continuity. This is shown for the superficial boundary in the reflection lines [6], where nearly $G^2$ smoothness is found for organic and smoothly blended portions of the structures (fig. 14). Also, structural parametric continuity is observed in the smooth profiles of the trabecular view, where inner sections and structural cells of the vectorial solid domains are arbitrarily sampled (fig. 14). Different smoothing configurations can be defined by altering the medial shells subdivision for mixed sharp and organically blended sub-portions, as in conventional smoothing groups. The construction of fully-coupled geometries, e.g. n-way-junctions, accounting for both luminal and wall multi-compartments are simultaneously generated, determining a conforming multi-compartmental domain fig. 14.

6.2 Polygonal Surface Meshes

A set of benchmark polygonal meshes are parametrised as reference (fig. 16). The luminal scaffolding recovers the underlying shape by fitting the mesh geometries with high accuracy (table 2) with respect to the reference boundary surface. Complex structures
Fig. 15. Compactness of the Parametrisation – representative examples: (a) Solid NURBS scaffolding: exact geometrical domain - sectioning inner trabecular view. Superficial degradation for increasing coarsening.

with multiple busy branching patterns are compactly parametrised with minimal element scaffoldings. Free-form cuboids of the conforming scaffolding recover the geometrical embedding of the underlying structure with localised deviations and minor distortions for high-curvature regions. The spatial partitions of junctions are automatically determined for busy skeletal branch-points. The automatic mapping of the scaffolding initially produced asymmetric quadrants and projected irregular quad-based segmentations on the boundary surface, especially for busy junctions with severe changes in size and shape. The resulting smoothness and continuity of the parametrised solid structures is shown in the reflection lines for the outer boundary and in the trabecular view for the innermost region in fig. 16. Nearly $G^2$ smoothness is achieved globally, and high structural regularity of the lattice is obtained in the form of an organic continuum. In the neighbourhood of extraordinary vertices, the solid scaffolding exhibits $G^1$ smoothness and continuity,

Fig. 16. Gallery of Solid Parametrised Geometries from Polygonal Surface Meshes – Explosion view, reflection lines and inner solid trabecular view. Nearly \(G^2\) smoothness and parametric continuity overall for boundaries and interfaces with organic profiles.

whereas pure positional continuity \((G^0)\) is observed exactly for the extraordinary vertices. Representative structures are parametrised using state-of-the-art hexahedral meshing [44] in fig. 17. Higher compactness and higher accuracy is observed for the proposed approach with respect to linear-element hexahedral meshes. Note that a further NURBS-based parametrisation is required in [44] prior to employing the hexahedral mesh in IGA.
6.3 Anatomical Structures from Clinical Imaging

Anatomical structures from volumetric scans are parametrised using the introduced scaffolding (fig. 18). The compact parametrisation produced a minimal luminal scaffolding comprising exactly 4 elements per branch. Tubular structures with arbitrary branching and connectivity patterns are accurately recovered (table 3) for the elongation of the branches. Also, irregular and convoluted tubular profiles as well as size-varying junctions are captured by the solid scaffolding with an organic outline using an optimal smoothing and fitting strategy. Nearly $G^2$ smoothness and continuity is achieved globally, by preserving local sharp features at the anatomical inlets and outlets allowing for boundary conditions in bio-mechanic computational simulations. Similar tubular structures are parametrised in previous work [77, 83], where elongated portions employ hexahedral meshes with dense cross-sectional subdivisions. In these studies, neither data-driven, nor generic parametric form is given for bifurcations and busy junctions, which are conversely modelled.
Fig. 18. Gallery of Anatomical Structures Parametrised from Volumetric Scans. Contours, slice intersections, solid NURBS scaffolding with reflection lines and inner solid trabecular views. Scalable parametrisation to large anatomical structures.

Table 3. Tracing anatomy from volumetric imaging: features of parametrised structures. Input scan: Imaging modality, \( v \) voxel size (mm). Solid NURBS Scaffolding: \( |H_3| \) total cubic-degree elements; \( |P| \) total control points in the multi-patch lattice; the computational time (s); geometrical parametrisation error (mm) is reported mean±sd. Hausdorff distance (\( \varepsilon_{95} \)).

with a dictionary of user-defined branching templates. In [83], the parametrised anatomical structures reach circumferential \( G^1 \) smoothness and continuity, whereas junctions locally exhibits sharp creases and longitudinal discontinuities.
6.4 Isogeometric Analysis Simulations

Representative computational problems are considered as proof-of-concept IGA applications to validate the parametrised scaffolding. A linear elasticity problem [4] is solved considering the Plate (CAD) and Stent (CAD) structures, as well as the Bunny (Mesh) geometry. In this case, boundary conditions and simulated solid deformations are shown in fig. 19. A steady-state fluid problem [31] is solved for representative luminal synthetic junctions, as well as for BrainNet 1 anatomical structure. Boundary conditions and simulation solution profiles of pressure and flow distributions are shown in fig. 19. Lastly, the Maxwell eigenvalue problem [79] is solved for Genus3 and Kitten (Mesh), as well as for the Egg (Synthetic) structure. In this case a set of eigenfunctions and the associated distributions are shown for both luminal and hollow wall geometries in fig. 19. All simulations are performed using [25], and the computational time as well as the memory footprint are provided in fig. 20. The scalability of IGA simulations and associated performance is also evaluated on equivalent denser lattices. An iterative cascade of conforming domain subdivisions (fig. 20) is progressively performed for the considered geometries, achieving comparable density as in hexahedral meshes [28, 29, 44, 75].

Successful simulations converged for all our scaffolding parametrisations (fig. 20), with smooth, continuous and consistent solution profiles. The introduced framework exhibits low computational time and minimal memory footprint. As in fig. 20, performance benchmarks shows a quadratic trend for increasing density of the lattice, suggesting improved scalability for structures parametrised with the introduced scaffolding. Equivalent hexahedral meshes determined a progressive increase of elements per conforming subdivision, resulting in a parametric lattice of substantially higher density. In this case, simulations only converged for meshes with less than 1.5k elements, as the memory footprint determined the limiting factor for the adopted IGA engine and solver. All simulations were computed on a single-core CPU 3.60 GHz with 64GB RAM machine.
7 DISCUSSIONS AND CONCLUSION

This work introduced a novel scaffolding framework to trace 3D structures with solid NURBS elements for computational simulations using isogeometric analysis.

Results obtained from different input data showed the scaffolding framework is able to compactly generalise for the parametrisation of arbitrarily complex structures with minimal elements and low parametric density. A novel interfacing configuration was introduced, i.e., the quadrilateral junction simplex, modelling the spatial partitioning of generic junctions for an underlying network of arbitrary connectivity patterns. Conforming and data-driven fitting strategies were presented to determine the geometrical embedding of the scaffolding with (semi-)automatic pipelines for polygonal surface meshes and volumetric image-based data, respectively. A novel solid smoothing paradigm is devised for the scaffolding lattice to obtain higher than positional geometric and parametric continuity at the interfaces and at the external boundaries of the structures, globally recovering an organic shape in the form of a continuum.

State-of-the-art tracing techniques employ raster (un-)structured polyhedral meshes to define the innermost lattice of 3D solid objects. Despite these intrinsically differ from parametric NURBS geometries, both qualitative and quantitative evaluations are proposed for the introduced framework based on analogies with the resulting scaffolding elements, lattice density, computational time and accuracy of fitted geometries.

To recover negligible geometrical deviations, tetrahedral meshes for conventional finite-element analyses [67] required a dense tessellation of elements and vertices, which differs by several orders of magnitude to the proposed parametrisation. Geometrical degradation is observed for iso-parametric optimised meshes, in particular for organic synthetic shapes and CAD designs with irregular and organic shapes.
The compactness of the introduced scaffolding was validated also on irregular geometries form 3D tessellated surfaces, where the resulting density of control points in the solid lattice was considerably lower than the input surface vertices. By leveraging geodesic strategies and a conforming sampling, the proposed scaffolding parametrisation reported high geometrical accuracy with respect to the reference geometries, with minor deviations for sharp and high-curvature features. Smoothness of the parametrised structures achieved nearly $G^2$ continuity globally.

Similarly, convoluted anatomical structures were compactly parametrised from volumetric imaging data with a fully automatic pipeline. Conforming fitting strategies based on geodesics and computer vision algorithms reported minor geometric deviations comparable to the input data resolution. Smoothness and continuity of the parametrised biological structures achieved an organic profile underlying a homogeneous medium in the form of a continuum.

Several IGA computational simulations validated the compatibility of the parametrised scaffolding with benchmarking performance. The simulations scalability was evaluated on equivalent hexahedral meshes obtained with cascades of conforming domain subdivisions to achieve similar element density as in state-of-the-art techniques [44]. IGA simulations successfully converged for the proposed scaffolding framework in all cases, with smooth, continuous and consistent solution profiles. The memory footprint, however, determined the limiting factor for simulations on equivalent hexahedral tessellations, with a quadratic trend for increasing density of the meshes.

Previous studies on hexahedral meshes [28, 44, 75], sought a solid re-parametrisation from raster surface geometries as a viable option towards an IGA-compatible domain. In similar CAD applications, the input tessellated geometry employed in finite-element analyses is often even obtained from rasterising an original vectorial design. For the sake of finite-element analyses, such re-parametrisation results in a convoluted and design-wise inefficient approach, specifically when IGA is used. Although mesh degradation can be mitigated with denser lattices, the migration from a parametric continuous domain to finite-resolution meshes introduces geometrical approximations and downgrades higher degrees of continuity to a pure positional one. Moreover, generic tetrahedral or hexahedral-dominant meshes cannot be directly fed to IGA, since all mesh elements require a conforming cuboid topology. Any other cell type in the mesh, e.g. pyramidal or wedge-like elements, invalidate the computational domain when a Galerkin discretisation [22] is considered for IGA. Given the affinity of linear-element cuboid hexahedral meshes with tensors of splines, a parametric equivalent can be determined. However, fitting NURBS cuboids \textit{a-posteriori} results in a dramatic increase of control points density for higher-degree spline elements. By elevating a linear-degree cuboid (minimal lattice of 8 control points) to an equivalent of cubic-degree (minimal lattice of 64 control points) the lattice density increases by 700% for the individual cell. Such increase of lattice density does not introduce, per se, higher degrees of continuity at the boundaries and interfaces of the solid mesh, instead the latter would simply remain positional ($G^0$) in the absence of a solid smoothing strategy. From an IGA-conforming perspective, applying the required parametric constraints to an unstructured solid mesh may result in a complete dependency of all univariate components, i.e. along $u$, $v$, and $w$ in all elements, with limited parametrisation flexibility with respect to the introduced scaffolding. Also, without an organised aggregation strategy, the scalability and simulation performance advantage observed on compact representations is dramatically diluted against dense tessellations, ultimately resulting in prohibitive or infeasible finite-element computations.

Based on the introduced framework, we argue that a streamlined solid design for finite-element analysis with IGA should rather begin with a consistent construction of a conforming scaffolding. In the general form, this could leverage similar graphic user-interfaces, modelling routines and virtual environments employed for the construction of more complex composite CAD geometries. This process would make use of guided and semi-automatic interactions for industrial and engineering designs, as in commercially available software, where modelling geometries rely on interactive user experiences. Nonetheless, simpler geometries may benefit from a more streamlined and fully-automatic scaffolding pipeline (e.g. anatomical structures), which can dramatically impact on in-silico medicine and digital twins formulations on large scale, addressing complex systems, diverse physical scenarios and continuous solutions of PDEs.

\textit{Limitations and Future Work.} Current limitations of the introduced scaffolding framework stand in automatically mapping on reference surface meshes complex junction partitions for particularly busy branching patterns. Although the existence of the junction simplex is guaranteed [73], the overly compact geometrical embedding may result counter-intuitive and difficult to visualise, especially
for the parametrisation of shape-varying structures as in complex polygonal tessellations. As described in appendices A and B, alternative IGA-compatible scaffolding configurations are feasible, and may locally accommodate for geometrical simplifications and topological adjustments. A simplified junction partition, e.g. the *grafting scaffolding* in appendix B, can be developed for a non-minimal yet highly compact scaffolding, which locally decomposes the busy junctions with extra cuts and interleaving elements, diluting therefore the cascade of bisections in a more regular and distributed fashion. Also, a more flexible formulation of the quadrilateral junction simplexes may locally relax the introduced geometrical and directional embedding to better model irregular and size-varying branching patterns. On the one hand, this would improve the accuracy of the in-house fitting paradigm for polygonal structures with a minimal distortion parametrisation of the boundary surface, e.g. adopting standard UV-mapping and seam-cuts unwrapping techniques [42]. On the other hand, a more regular and distributed branching pattern of the junction simplex would reduce the valence of extraordinary vertices, therefore improving the geometrical smoothness and parametric continuity close to the singularities. Although the introduced solid smoothing paradigm achieves nearly $G^2$ geometrical smoothness and parametric continuity for the entirety of the solid scaffolding, a minor degradation is observed at the medial locus and in the neighbourhood of extraordinary vertices. This is however in line with the considerations of [70] for topological singularities. The continuity observed in our parametrised geometries replicates the same experimental outcomes in [5, 70] for vertices of varying valence. The devised smoothing strategy builds on the same averaging scheme, here with ad-hoc topological variations for multi-patch solid lattices. Based on experimental observations, the introduced smoothing paradigm can be similarly applied also to solid multi-patch meshes which exhibit a different scaffolding configuration, comprising (un-)structured hexahedral cuboid elements. As shown in appendix B, both *Cross* and *Frame* geometries, exhibit a face-wise 6-connected scaffolding, similarly to hexahedral meshes, where each branch is extruded, without employing a quadratic junction simplex. An organised structured and conformal aggregation strategy would potentially convert a cuboid hexahedral mesh into a compact scaffolding by means of an adaptive trade-off between splitting, refining and merging of cuboid elements. This would represent a viable strategy for composite geometries requiring extensive sub-block decomposition [20, 48, 75, 81], without further geometric re-parametrisation. An adaptive refinement may also address individual vectorial elements; recent IGA developments support hierarchical and T-NURBS elements [8, 11, 30, 34, 35]. With this view, a local lattice refinement may be selectively employed in the neighbourhood of discontinuous regions and singular points (i.e. extraordinary vertices) with the aim of improving the local geometrical support, the smoothness and parametric continuity and towards adaptive degrees of freedom for computational simulations. Adaptive and hierarchical local subdivisions of the vectorial elements [11, 30] could optimally circumvent the conforming propagation of the lattice refinement, as in a continuous Galerking method [18, 21], without globally affecting the topological formulation and the parametric arrangement of the entire scaffolding. Prospectively, the extension to hierarchical NURBS scaffolding elements could be further coupled with higher degrees splines and an optimal solid smoothing strategy along the lines of [16, 69] where localised hierarchical refinements follow geometrical adjustments based on non-uniform knot vectors and on the diagonalisation of the lattice subdivision matrices.

**Concluding Remarks.** The introduced scaffolding framework constitutes a fundamental advance towards bridging the gap between compactly tracing vectorial solid structures and continuous-domain computational simulations. We believe our contributions could further stimulate and inspire novel developments with revolutionising applications on multi-disciplinary grounds for next-generation computational simulations.

### A WALL SCAFFOLDING CONSTRUCTION

The wall scaffolding is modelled as an extension of the luminal one (section 3.2). It comprises the organised set of vectorial elements occupying the hollow volumetric space enclosing a luminal region, e.g. a set of connecting hollow pipes or hollow chambers with thin or thick walls, in the form of a solid shell (fig. 21). The wall scaffolding can be considered either separately, or additionally coupled with a luminal scaffolding.

**Minimal Elements.** The minimal number of elements depends on the complexity of the underlying structure. Building on concepts introduced in section 3.2, the wall scaffolding requires 8 elements longitudinally surrounding each branch. Additional 4 elements are required when one end of any branch is closed, i.e. the wall covers and closes the terminal portion of the hollow structure. In

Fig. 21. Wall Scaffolding Construction: (a) 4-way-junction: 8 elements per elongated branch forming an octagonal ring; (b) Additional capping elements per terminal branch. (c) Boundaries and conforming interfaces of adjacent elements facing the parametric directions; (d) Smooth limit geometry; (e) Egg-like thin wall as closed hollow chamber: scaffolding comprising two sets of capping elements.

general, the elements of the wall scaffolding are proportional to the boundary sides of a virtually nested luminal scaffolding, and the construction of the wall resembles a conforming extrusion along the luminal interfaces.

**Arrangement and Adjacency.** In general the wall scaffolding cross-sectionally configures the elements of each elongated branch in an octagonal ring (fig. 21). As in the luminal region, these elements are elongated along the parametric direction \( w \), mapping the longitudinal direction of a branch. The parametric directions \( u \) and \( v \) of the wall scaffolding independently map a pseudo-circumferential direction, and a pseudo-radial direction, respectively, relative to the elongation of the branch. Each adjacent element of the wall scaffolding has interfaces facing the pseudo-circumferential direction \( u \). In the absence of a coupled luminal scaffolding, two sets of boundaries are determined, both facing the pseudo-radial direction \( v \); one facing the interior hollow luminal region, another facing the exterior of the wall structure. However, when the wall is coupled with a luminal scaffolding, both scaffoldings share a mutual set of interfaces, constituting a complementary and multi-compartmental nested structure.

For a closed terminal branch the wall scaffolding additionally introduces 4 capping elements (fig. 21). These form a quadrant-like configuration and their parametric arrangement is consistent with a luminal scaffolding element, i.e. \( u \) and \( v \) no longer map independently the pseudo-circumferential and the pseudo-radial directions, respectively. Each capping element determines at least 4 interfaces. Two contiguous sides (one facing \( u \), and the other facing \( v \)) are shared with 2 adjacent capping elements; whereas other two contiguous sides (one facing \( u \), and the other facing \( v \), on opposite directions) are shared with 2 adjacent elongated elements.

Without a coupled luminal region, both sides of the capping element facing \( w \) are referred as boundaries, each belonging to the interior and to the exterior wall boundaries, respectively. Conversely, with a coupled luminal scaffolding, each capping element shares an extra interface between the nested scaffoldings.

The formulation of a wall scaffolding configuration at the interface of a \( n \)-way-junction is a straightforward extension of the luminal quadrilateral junction simplex \( Q \) in section 3.2. Both interior (\( Q_{int} \)) and exterior (\( Q_{ext} \)) simplexes of the of the wall scaffolding replicate the same configuration and differ in size, accounting for the pseudo-radial thickness of the wall. In this case, the resulting set of interfaces facing \( w \) is determined by connecting one-to-one each vertex of \( Q_{int} \) with the respective vertex of \( Q_{ext} \), and the cross-sectional octagonal configuration is kept for all the branches.

**Conforming Constraints.** The conforming conditions depend on coupling the wall with a nested luminal scaffolding.

For an uncoupled open wall scaffolding, no mutual dependency is determined for the parametric components of each element along the different parametric directions. Conversely, for an uncoupled closed wall scaffolding, i.e. in presence of capping elements, the parametric components of each element along \( u_{(wall\ branch)} \) and \( v_{(wall\ branch)} \) are equivalent, whereas only the parametric component along \( w_{(wall\ branch)} \) is independent. The capping elements of each terminal branch, however, make exception: all the parametric components are dependent and mutually equivalent along \( (u, v, w)_{(wall\ cap)} \) to \( (u, v)_{(wall\ branch)} \).

When a wall scaffolding is coupled with a nested luminal one, the conforming constraints are mutually related between scaffoldings. In particular, for a coupled closed wall scaffolding, the parametric components of each element along \( (u, v)_{(wall\ branch)} \) coincide with those of \( (u, v)_{(luminal)} \). Also, the parametric components along \( w_{(wall\ branch)} \) coincide with those along \( w_{(luminal)} \). All the capping elements of the closed wall scaffolding are mutually dependent, i.e. \( (u, v, w)_{(wall\ cap)} \) coincide to \( (u, v)_{(wall\ branch)} \) as well as to...
Fig. 22. Other Scaffolding Construction: (a) Cross and (b) Frame geometries with 6-face-connectivity scaffolding. (c) Exceptionally reduced planar scaffolding for bifurcating structures. (d) Associated configuration of the wall scaffolding. (e) Grafting scaffolding: Pinocchio geometry with primary and secondary branches; (f) Pinocchio topological variation, arrangement and adjacency.

\[(u, v)_{\text{luminal}}\]. Lastly, for a coupled open wall scaffolding, the parametric components of each element along \(u_{\text{wall branch}}\) coincide with those of \((u, v)_{\text{luminal}}\), whereas \(v_{\text{wall branch}}\) and \(w_{\text{wall branch}}\) are independent.

B OTHER CONFORMING SCAFFOLDING CONFIGURATIONS

For completeness, alternative conforming scaffolding configurations are simply mentioned below. These may result in local deviations from the introduced framework with minor topological and parametric variations affecting the density of vectorial elements, their arrangement and the associated conforming constraints.

By way of example, a 6-face-connectivity scaffolding is shown in fig. 22, for the synthetic Cross and Frame geometries. Starting from an innermost cube, such configuration consist of an independent conformal extrusion along each boundary face into a set of adjacent vectorial elements. Note that the extension of such configuration includes structured (e.g. voxel-based) or unstructured hexahedral meshing approaches.

Based on section 3.2, a planar scaffolding exceptionally halves the number of vectorial elements per branch. This is suitable for isolated 3-way-junctions as in fig. 22. Alternatively, in case of a network, this configuration is applicable only if all the junctions are either bifurcations, or they exhibit a planar arrangement. In such case, note that the structural torsional twist along connecting branches of the luminal scaffolding may increase up to \(\theta_{\text{max}} = \frac{\pi}{2}\) by adopting the same geometrical embedding in section 4. Note that such exceptional reduction can affect the configuration of a coupled wall scaffolding, or symmetrical and modular structures (e.g. Gear).

Lastly, a grafting scaffolding defines a hierarchical branching relationship and labels branches of the skeleton as primary, secondary, and so on (e.g. based on size), these being interleaved by cross-sectional cuts in fig. 22. This configuration is suitable for particularly busy or spatially close junctions by locally simplifying the interfacing simplexes. Note that, the grafting configuration reduces the scaffolding elements of the secondary branch relative to the primary one, with potential limitations for downstream branching and connectivity patterns.
