Introduction

Subcellular localization of mRNAs can locally control the protein composition of distinct regions within the cell. In this study, we investigate whether the axonal localization of neuronal mRNAs is regulated by extracellular stimuli. By profiling axonal levels of 50 mRNAs detected in regenerating adult sensory axons, we show that neurotrophins can increase and decrease levels of axonal mRNAs. Neurotrophins (nerve growth factor, brain-derived neurotrophic factor, and neurotrophin-3) regulate axonal mRNA levels and use distinct downstream signals to localize individual mRNAs. However, myelin-associated glycoprotein and semaphorin 3A regulate axonal levels of different mRNAs and elicit the opposite effect on axonal mRNA levels from those observed with neurotrophins. The axonal mRNAs accumulate at or are depleted from points of ligand stimulation along the axons. The translation product of a chimeric green fluorescent protein-β-actin mRNA showed similar accumulation or depletion adjacent to stimuli that increase or decrease axonal levels of endogenous β-actin mRNA. Thus, extracellular ligands can regulate protein generation within subcellular regions by specifically altering the localized levels of particular mRNAs.
shown to regulate axonal protein synthesis (Campbell and Holt, 1999). In the present study, we show that the levels of individual axonal mRNAs are differentially regulated by the local stimulation of axons with growth-promoting and growth-inhibiting stimuli. Quantitative analyses of axonal mRNAs showed that nerve growth factor (NGF), brain-derived neurotrophic factor (BDNF), neurotrophin-3 (NT3), myelin-associated glycoprotein (MAG), and Sema3A can specifically increase or decrease levels of individual transcripts. These alterations in axonal mRNA levels were accompanied by opposite changes in the cell body mRNA levels, suggesting that ligand-dependent alterations in anterograde transport rates exist. With in situ hybridization and heterologous expression of a chimeric mRNA containing the rat β-actin mRNA localization element, the alterations in axonal mRNA levels seen by quantitative analyses correspond to the relative enrichment or depletion of individual mRNAs from axonal regions directly adjacent to ligand sources. These findings argue that diverse extracellular signals bidirectionally regulate the transport of numerous mRNAs within axons to influence local protein synthesis.

Results

Scope of proteins locally synthesized in the rat sensory axons

We previously used a proteomics approach to identify locally synthesized proteins from cultures of adult rat dorsal root ganglion (DRG) neurons (Willis et al., 2005). This approach was limited to the most abundant axonally synthesized proteins. Because we were able to view only a fraction of the axonal mRNAs using this method, we reasoned that a more global assessment of axonal mRNA content would be needed to test for the specific regulation of axonal mRNA localization. For this, axonal RNA was isolated from dissociated cultures of DRG neurons after 20–22 h in vitro as previously described (Zheng et al., 2001). The L4-5 DRGs were conditioned by in vivo sciatic nerve crush 7 d before culture. These injury-conditioned sensory neurons show rapid transcription-independent, translation-dependent process outgrowth over 24 h in culture (Smith and Skene, 1997; Twiss et al., 2000). The purity of axonal preparations was verified by the absence of γ-actin and microtubule-associated protein 2 mRNAs (Fig. S1, available at http://www.jcb.org/cgi/content/full/jcb.200703209/DC1; Zheng et al., 2001; Willis et al., 2005). Amplified cDNAs prepared from axonal RNAs were used to hybridize to Atlas cDNA arrays containing ~4,000 rat cDNAs. Localized mRNAs detected from hybridizations of four separate axonal preparations are summarized in Table S1. According to these data, the injury-conditioned DRG axons have the capacity to synthesize >200 different proteins, including transmembrane proteins (e.g., Kv3.1a and HCN4) and components of the translational machinery (e.g., ribosomal proteins) that were not detected in our previous proteomics screen (Willis et al., 2005).

Axonal mRNA levels can be positively and negatively regulated by peripheral stimulation with chemotropic agents

Guidance cues that invoke axon turning or collapse have been shown to regulate axonal protein synthesis (Campbell and Holt, 2001, 2003; Ming et al., 2002; Piper et al., 2005). To determine whether axonal mRNA localization is specifically regulated in the DRG neurons, we asked whether the local application of growth-promoting or growth-inhibiting stimuli to DRG axons can alter the localization of individual mRNAs. A panel of 50 axonal mRNAs from the aforementioned array data and a previous proteomics study (Willis et al., 2005), which broadly represents axonal mRNAs encoding different protein types, was used for these analyses. Neurotrophins were chosen for the growth-promoting ligands because their TrkA, TrkB, and TrkC receptors are expressed by all of the DRG neurons (Snider, 1994). Sema3A and MAG were used as growth-inhibitory stimuli because these ligands induce axonal retraction or repulsion in rat DRG neurons (Shen et al., 1998; Li et al., 2004). The axonal compartment was exposed to ligands immobilized on microparticles for 4 h in the presence of the RNA polymerase II inhibitor 5,6-dichlorobenzimidazole riboside (DRB). Microparticles with immobilized BSA, AP, or human IgG Fc domain were used as controls for the neurotrophin, Sema3A, and MAG, respectively. Axonal mRNA levels for each of the 50 transcripts were determined using axonal RNA isolates for reverse transcription followed by quantitative PCR (qPCR). The qPCR results are detailed in Table I. These data show both ligand and transcript specificity for the regulation of axonal mRNA levels.

Fig. 1 summarizes changes in axonal levels for a few mRNAs to illustrate the specificity of these ligand-dependent responses. Note that each stimulus can increase or decrease axonal levels of an individual mRNA. For the neurotrophins, NGF and BDNF showed an overall similar regulation of axonal mRNA levels except for 43-kD growth-associated protein (GAP-43) mRNA, which was uniquely affected by NGF (Fig. 1 A). NT3 modulation of axonal mRNA levels appeared distinct from NGF and BDNF. For example, axonal levels of the mRNA encoding the Kv3.1a potassium channel was decreased by NGF and BDNF, but NT3 increased axonal levels of Kv3.1a mRNA (Fig. 1 A). Similar to the neurotrophins, MAG and Sema3A increased and decreased the localization of individual axonal mRNAs (Fig. 1 B). With the exception of vimentin mRNA, MAG and Sema3A altered axonal mRNA levels distinctly from the neurotrophins (Fig. 1 B and Table I). For example, Sema3A and MAG decreased axonal β-actin mRNA levels, whereas the neurotrophins consistently increased axonal β-actin mRNA levels. Several transcripts that were not responsive to the neurotrophins showed altered axonal levels with MAG and/or Sema3A (Table I). Interestingly, many of the mRNAs tested showed no significant change (P > 0.01) in response to the 4-h ligand stimulation (Table I). This result, combined with the differences in axonal mRNA levels seen among the individual neurotrophins, indicates that the regulation of mRNA localization is highly specific at the level of individual transcripts and for ligands that activate similar intracellular signaling pathways.

Ligand-induced changes in axonal mRNAs change cell body mRNA content

Over the 4-h period used to stimulate the aforementioned axons, DRB decreased new RNA synthesis >90% based on the incorporation of α-[32P]UTP into RNA isolated from cultures of...

qPCR data for the axonal mRNAs tested for axonal level modulation by NGF, BDNF, NT3, MAG, and Sema3A are tabulated. Axonal levels of the mRNAs are compared with axons treated with controls (8SA for NGF, BDNF, and NT3; IgG-Fc for MAG; and AP for Sema3A) and are displayed ± SD from three replicates. Values in bold indicate differences that were statistically significant based on P < 0.01 by the student Newman-Keuls test. The other values are not statistically significant (P ≥ 0.01).
injury-conditioned DRGs (Fig. S2 A, available at http://www.jcb.org/cgi/content/full/jcb.200703209/DC1). Although we cannot exclude the possibility that alterations in axonal mRNA stability contributed to the changes in axonal mRNA levels, these metabolic labeling experiments suggest that chemotropic agents can alter the localization of existing mRNA populations. If this is the case, any transport-dependent changes in axonal mRNA levels should be accompanied by an opposite change in the levels of that transcript in the cell body. Although our previous analysis of cytoskeletal mRNAs did not show depletion of cell body levels after NGF-induced increases in mRNA levels in the axons, the high expression of cytoskeletal mRNAs in the DRG cultures could complicate the detection of cell body depletion during this and previous short-term experiments (Willis et al., 2005). To more rigorously test for ligand-dependent alterations in axonal mRNA content, we extended treatment duration from 4 to 12 h and evaluated axonal levels of a subset of mRNAs that showed increased or decreased axonal levels with NGF (Fig. 2). qPCR analyses of cell body and axonal RNA content showed that the decrease in axonal levels of Cav1.2 and Kv3.1a mRNAs seen after NGF exposure resulted in a statistically significant increase (P ≤ 0.01) in the cell body content of these mRNAs. In contrast, increased axonal levels of peripherin, RP-L22, RP-S17, and thymosin β4 mRNAs resulted in decreased cell body mRNA content (Fig. 2). These data suggest that the sensory neurons draw on a pool of preexisting mRNAs in the cell body to alter the delivery of individual mRNAs into the axons in response to ligand stimulation. In addition, these data indicate that extracellular signals can lead to a new steady state in the distribution of specific mRNAs between the cell body and axon that is likely independent of transcription.

RNAs are transported on microfilaments in fibroblasts, whereas most other cellular systems, including neurons, have been shown to use microtubules for long-range transport of mRNAs (Sundell and Singer, 1990; Carson et al., 1997; Brumwell et al., 2002; Oleynikov and Singer, 2003; Shan et al., 2003; Chang et al., 2006). To determine whether the neurotrophin-dependent changes in axonal mRNA levels in Fig. 1 A require intact cytoskeleton, dissociated cultures were pretreated with cytochalasin D or colchicine to disrupt microfilaments or microtubules, respectively. For this analysis, we examined a subset of the transcripts

Figure 1. Axonal stimulation with growth-promoting and growth-inhibiting stimuli alters axonal mRNA localization. (A and B) The changes in axonal levels of representative mRNAs in response to NGF, BDNF, and NT-3 (A) or MAG-Fc and Sema3A-AP (B) from Table I are graphically illustrated. Positive values indicate an increase in axonal mRNA content, and negative values indicate a decrease in axonal mRNA content detected by qPCR. The axonal mRNA values for neurotrophins are expressed relative to axons treated with BSA. Values for MAG are expressed relative to human IgG Fc, and those for Sema3A are expressed relative to AP (there were no statistically significant differences between the Fc and AP controls; not depicted). Error bars represent the SD of three replicate experiments with each sample measured in quadruplicate. Significance was calculated based on P ≤ 0.01 by a student Newman-Keul test compared with the control. Note that the neurotrophins, MAG, and Sema3A selectively increase or decrease the transport of individual mRNAs. No statistically significant changes were seen in axonal levels of αβ crystallin, grp78/Bip, or HCN4 mRNAs with NGF, BDNF, or NT3 treatments. No statistically significant changes were seen in axonal levels of GAP43, Kv3.1α, or peripherin mRNAs with MAG or Sema3A treatments.
shown in Table I that was comprised of five mRNAs with increased transport with NGF, five mRNAs with decreased transport with NGF, and five mRNAs with no response to NGF. The disruption of microfilaments decreased the NGF-dependent alterations in axonal mRNA levels but not to the extent that was seen with the microtubule-depolymerizing agent (Fig. 3 A). Although colchicine treatment modestly reduced overall axonal mRNA levels, the NGF-induced changes in axonal levels were almost completely abolished by colchicine (Fig. 3 A). Specificity for the effect of colchicine on NGF-dependent RNA localization is indicated by the lack of any effect of colchicine or cytochalasin D on the nonresponding mRNAs (Fig. 3 A). These observations further suggest that neurotrophins regulate axonal mRNA levels by altering the rates of transport of mRNAs from the cell body.

A change in delivery of mRNAs into axons with peripheral stimulation could require that instructive signals from the axons be retrogradely transmitted to the neuronal cell body (or nucleus). To determine whether the aforementioned alterations for mRNA levels require stimulus localized to the axonal compartment, we compared axonal mRNA levels after the application of immobilized NGF to axons versus bath-applied NGF (i.e., soluble), which would simultaneously stimulate axonal and cell body compartments. Approximately equivalent levels of soluble versus immobilized ligand were applied based on our previous assessments of TrkA phosphorylation by the NGF microparticles (Willis et al., 2005). Roughly twofold more β-actin mRNA accumulated in the axons with local stimulation than with bath-applied NGF (Fig. 3 B). Peripherin and Kv3.1a mRNAs showed no response to bath-applied neurotrophins,
whereas axonal HCN4 mRNA appeared more sensitive to bath-applied NGF than localized ligand sources. With bath application of NGF, calreticulin, and HSP70 mRNAs, two transcripts that did not respond to localized NGF showed alterations in axonal mRNA levels, indicating that these transcripts uniquely respond to the soluble ligand (Fig. 3 B). Collectively, these data indicate that the stimulus derived from localized neurotrophin sources is qualitatively and quantitatively different from the nonlocalized stimulus of the soluble ligand.

Modulation of axonal mRNA localization through divergent signaling pathways

To determine the role of Trk receptors in neurotrophin-dependent axonal mRNA localization, cultures were pretreated with K252A at levels that specifically inhibit Trk tyrosine kinase activity (Tapley et al., 1992). For the mRNAs that increased with axonal NGF stimulation, K252A pretreated cultures showed axonal levels that were nearly indistinguishable from neurons exposed to control microparticles (Fig. 4 A). Axonal levels of the five nonresponding transcripts were not affected by K252A treatment (Fig. 4 A). Surprisingly, mRNAs with NGF-dependent decreases in axonal content showed a complete reversal, exhibiting increased axonal levels with Trk inhibition and peripheral NGF stimuli (Fig. 4 A). Both Kv3.1a and HCN4 mRNAs, for which levels were decreased by 1.5-fold in the axons treated with NGF, showed a one- to twofold increase in axonal levels in cultures treated with K252A (Fig. 4 A). This indicates that local sources of NGF can signal through Trk receptors to bidirectionally modulate the axonal localization of individual mRNAs.
The neurotrophin-dependent activation of phosphatidylinositol-3 kinase (PI3K) and Ras–MAPK pathways contribute to the local trophic and tropic effects of NGF and other neurotrophins (Segal, 2003). We used pretreatment with MEK1 and PI3K inhibitors (PD98059 and LY29004, respectively) to test whether these signaling pathways play a role in the neurotrophin-dependent regulation of axonal mRNA localization. The five mRNAs that previously did not respond to NGF remained unaffected overall by PD98059 and LY29004, indicating that basal activity of PI3K and MEK1 did not contribute to their axonal localization (Fig. 4 B). For most of the regulated mRNAs, NGF’s effects on their axonal levels were attenuated by inhibition of the MAPK pathway with PD98059 (Fig. 4 B). However, two transcripts behaved differently. The NGF-dependent attenuation of Kv3.1a mRNA’s axonal localization required PI3K activity but was unaffected by the MEK1 inhibitor (Fig. 4 B). The increased axonal localization of β-actin mRNA seen with NGF was attenuated by the inhibition of either PI3K or MEK1 (Fig. 4 B). All other mRNAs that localized in response to NGF (e.g., vimentin and peripherin) required MEK1 but not PI3K (Fig. 4 B). Thus, a single ligand can uniquely regulate the axonal localization of individual mRNAs using different downstream signaling pathways.

Focal ligand sources instruct the neuron where and when not to localize mRNAs within axons

Although extremely sensitive, the reverse transcription qPCR method used in Figs. 1–4 provides no information on where mRNAs are localized within the axon. Because axonal β-actin mRNA showed divergent regulation with growth-promoting versus growth-inhibiting stimuli and appeared more sensitive to localized ligand sources, we used the well-characterized localization elements of β-actin mRNA to drive the axonal localization of heterologous mRNAs encoding a reporter protein. For this, the 3′ untranslated region (UTR) of enhanced GFPNLs/myr (eGFPNLs/myr; Aakalu et al., 2001) was replaced with 3′ UTRs from the rat β-actin or γ-actin mRNAs (eGFPNLs/myr-β-actin and eGFPNLs/myr-γ-actin, respectively). β-actin mRNA 3′ UTR contains a zipcode element that directs the transport of this mRNA in fibroblasts, myocytes, and neurons; γ-actin mRNA does not contain any similar element, and the transcript is retained in the perinuclear region (Lawrence and Singer, 1986; Kislaskis et al., 1994; Bassell et al., 1998). To facilitate expression in the adult DRG neurons, we generated adenosviruses (AVs) that express these reporter cDNAs (AV-eGFPNLs/myr-γ-actin and AV-eGFPNLs/myr-β-actin). In injury-conditioned DRG cultures infected with AV-eGFPNLs/myr-γ-actin, reporter fluorescence accumulated in the cell body and did not extend into the axonal compartment (Fig. S3, available at http://www.jcb.org/cgi/content/full/jcb.200703209/DC1). In contrast, GFP signal was seen in the cell body and at foci along the axonal processes, including the growth cones in cultures infected with AV-eGFPNLs/myr-β-actin (Fig. S3). The myr domain of this eGFPNLs/myr construct likely restricts diffusion of the eGFP product in the axonal compartment, providing a measure of localized protein synthesis as previously reported (Aakalu et al., 2001). RT-PCR from axonal RNA also confirmed the differential localization of eGFPNLs/myr-β-actin versus eGFPNLs/myr-γ-actin mRNAs in the DRG cultures (unpublished data). Thus, similar to axons of developing cortical neurons (Zhang et al., 1999; Gu et al., 2002), the 3′ UTR of β-actin mRNA is sufficient for axonal localization in adult rat sensory neurons.

Because the β-actin 3′ UTR appeared to direct axonal localization of eGFP mRNA in the DRG cultures, we next considered whether axonal localization of eGFPNLs/myr-β-actin is modulated by growth-promoting and growth-inhibiting stimuli. Analyses of axons exposed to NGF microparticles showed that GFP signals under the control of β-actin 3′ UTR accumulated directly adjacent to the ligand source during a 50-min exposure (Fig. 5 A and Video 1, available at http://www.jcb.org/cgi/content/full/jcb.200703209/DC1). Axons typically showed a sprouting or turning response upon contact with NGF microparticles (Fig. S4). BSA microparticles did not affect the intensity of GFP signals or the directionality of axonal growth (Fig. S4). At the completion of a 50-min exposure, axonal GFP fluorescence was significantly greater adjacent to NGF when compared with BSA microparticles (5.29 ± 0.07-fold for NGF vs. BSA; P ≤ 0.001). Although there is an inherent experimental delay in when video sequences can be initiated with this approach (i.e., as the particles settle onto the coverslip), there was also a consistent increase in GFP fluorescence adjacent to NGF microparticles over the course of the imaging sequences (1.6 ± 0.09-fold for t = 50 vs. t = 0 min; P ≤ 0.001). Similar to the effects of kinase inhibitors upon the endogenous β-actin mRNA shown in Fig. 4, the inhibition of Trk or downstream MEK1 or PI3K activity prevented any GFP accumulation adjacent to the NGF source (Figs. 5 B and S4 and Video 2). Thus, the dynamic redistribution of mRNA likely directly impacts the translation and accumulation of protein.

Microtubule-depolymerizing agents were used to determine whether an increase in GFPNLs/myr-β-actin signals was the result of RNA accumulation at NGF sources. No NGF-dependent accumulation of GFP was seen in cultures exposed to colchicine (Fig. 5 C and Video 3, available at http://www.jcb.org/cgi/content/full/jcb.200703209/DC1). The continued increase in GFP signals in the growth cone (distal to NGF source) indicates that the colchicine treatment did not affect translation of the eGFPNLs/myr-β-actin mRNA that had already accumulated in the growth cone. Because colchicine completely blocked NGF-dependent increases in axonal β-actin mRNA levels in the qPCR experiments (Fig. 3 A), the majority of the increased GFP signals shown in Fig. 5 A can be attributed to the subcellular localization of eGFPNLs/myr-β-actin mRNA rather than to the translational activation of any eGFPNLs/myr-β-actin mRNA already residing within the axon.

Because microtubule depolymerization would alter both retrograde and anterograde transport, we tested whether the NGF effect on eGFPNLs/myr-β-actin required retrograde signaling. For this, DRG cultures were transfected with dynein heavy chain (Dync1h1) siRNAs (He et al., 2005). The transfected cultures showed a decrease of Dync1h1 protein, and transfected neurons showed a selective depletion of retrograde but not anterograde transport (Fig. S2 B and Video 4, available at
These siRNA-transfected neurons also showed no significant alteration (P > 0.05) in eGFP\textsuperscript{NLS/myr}\(\beta\)-actin signals over 50 min of exposure to NGF microparticles (0.91 ± 0.11-fold for NGF vs. BSA; Fig. 5 D). DRG cultures treated with erythro-9-(2-hydroxy-3-nonyl)adenine hydrochloride (EHNA), which has been shown to inhibit dynein ATPase activity (Ekstrom and Kanje, 1984; Shpetner et al., 1988), had similar depletion of retrograde transport (Video 5) and showed no significant change (P > 0.05) in axonal GFP fluorescence in response to NGF (0.95 ± 0.10-fold for NGF vs. BSA). Thus, the NGF-dependent increase in localization of the axonal reporter mRNA appears to require retrograde transport.

To determine how growth-inhibiting stimuli can deplete axonal \(\beta\)-actin mRNA levels, we examined the effect of immobilized MAG on axonal GFP signals in AV-eGFP\textsuperscript{NLS/myr}\(\beta\)-actin–infected DRG cultures. GFP signals were relatively excluded from axonal regions adjacent to MAG sources (Fig. 6 A and Video 6, available at http://www.jcb.org/cgi/content/full/jcb.200703209/DC1). After 50-min exposure to microparticles, GFP signals were significantly decreased with MAG-Fc microparticles when compared with the control IgG Fc microparticles (0.68 ± 0.1-fold for MAG-Fc vs. IgG Fc; P ≤ 0.001). The eGFP\textsuperscript{NLS/myr}\(\beta\)-actin translation product was relatively depleted from the vicinity of MAG-Fc (Fig. S4); this focal exclusion of GFP adjacent to MAG sources is likely why MAG caused only a small reduction in \(\beta\)-actin mRNA by qPCR. In contrast to NGF’s effects on eGFP\textsuperscript{NLS/myr}\(\beta\)-actin signals, a statistically significant attenuation of axonal GFP signals adjacent to MAG stimuli was still seen when retrograde transport was inhibited with Dync1h1 siRNA (0.75 ± 0.07-fold for MAG vs. IgG Fc; P ≤ 0.01; Fig. 6 B) or EHNA (0.73 ± 0.12-fold for MAG vs. IgG Fc; P ≤ 0.01; not depicted). Thus, the MAG-dependent depletion of GFP signals appeared to be a local effect adjacent to axonal stimuli.
The growth-inhibitory effects of MAG can be overcome by elevating neuronal cAMP levels (Cai et al., 1999, 2001; Neumann et al., 2002). To determine whether the MAG-dependent changes in the localized production of eGFPNLS/myrβ-actin could be altered by cAMP, cultures were treated with a cell-permeable nonhydrolyzable cAMP analogue (dibutyral cAMP [db-cAMP]) before exposure of axons to immobilized MAG. In db-cAMP–treated cultures, eGFPNLS/myrβ-actin signals accumulated directly adjacent to the MAG microparticles (Fig. 6 C and Video 7, available at http://www.jcb.org/cgi/content/full/jcb.200703209/DC1). The GFP signals showed a significant increase adjacent to MAG-Fc microparticles after cAMP treatment when compared with IgG Fc control (4.47 ± 0.06-fold for MAG-Fc + db-cAMP vs. IgG Fc + db-cAMP; P ≈ 0.001), and, similar to the NGF response, axons turned acutely after contact with the MAG microparticles (Fig. 6 S4). Pretreatment with db-cAMP did not alter the response seen by contact with NGF or control microparticles (unpublished data).

**Ligand-dependent localization of endogenous axonal mRNAs**

FISH was used to determine whether focal stimulation of axons with growth-promoting versus growth-inhibiting ligands could similarly alter the local accumulation of endogenous mRNAs in these axons. For this, injury-conditioned DRGs were plated onto laminin-coated coverslips with adherent neurotrophin, MAG, and Sema3A microparticles. After 18 h in culture, cells were fixed and analyzed by FISH for mRNA and immunofluorescence for neurofilament. Differences in mRNA signal intensity adjacent to the immobilized agent were specific both at the level of the transcript and ligand. Consistent with the transfected eGFPNLS/myrβ-actin, endogenous β-actin mRNA was enriched adjacent to neurotrophin sources and decreased adjacent to MAG and Sema3A sources (Fig. 7 A). The disparity between the responses elicited by NGF and NT3 seen in the qPCR experiments for peripherin and Kv3.1a mRNAs was also evident in the localization of these transcripts along axons exposed to immobilized NGF and NT3. Peripherin mRNA increased at the site of NGF stimuli but decreased adjacent to NT3 stimuli (Fig. 7 B). The opposite pattern was seen with Kv3.1a mRNA: FISH signals for Kv3.1a were decreased adjacent to NGF stimuli but increased adjacent to NT3 stimuli (Fig. 7 C). Together, these findings show that the exquisite ligand specificity for mRNA localization seen in the qPCR experiments corresponded to localized accumulation or depletion of individual transcripts directly at the site of ligand exposure.

**Discussion**

Targeting mRNAs and translational machinery to subcellular loci is being increasingly recognized as a means to locally control the protein composition of cellular domains. Modulating the levels...
of individual mRNAs in different subcellular regions could alter the populations of proteins generated in these regions by locally altering the availability of templates for the local translational machinery. Because of the distances separating neuronal processes from their cell body, neurons are an appealing cellular model for testing how local stimuli alter the trafficking of mRNAs into subcellular regions. Both the dendritic and axonal compartments of neurons have been used to study the localization of single transcripts, but the specificity of such changes has not been addressed for a broad population of mRNAs. Localized protein

Figure 7. Axonal mRNA levels are altered at the site of tropic stimulation. (A–C) Injury-conditioned DRGs were grown in the presence of focal immobilized sources of attractive or repulsive chemotropic agents for 18 h and analyzed by FISH for β-actin (A), peripherin (B), or Kv3.1a mRNA (C). Representative differential interference contrast and fluorescent signals for mRNAs are illustrated for each indicated condition. The DRG processes were visualized by immunofluorescence for neurofilament heavy subunit (not depicted). The differential interference contrast images are focused on the microparticle to show the bead position relative to the axon. The bar graphs show relative axonal mRNA signal intensity in 5-μm bins that were normalized to the mean signal intensity across the axon (an x-axis value of 0 indicates the 5-μm bin that bisected the microparticle; proximal negative numbers indicate the proximal axon, and positive numbers indicate the distal axon). Quantitative data were obtained from three separate experiments, and error bars represent the SD of 30 individual axons measured over these repetitions by a blinded observer. Fold differences are indicated in bins that are significantly different compared with the most proximal segment (P ≤ 0.01; student Newman-Keul test). Bars, 5 μm.
synthesis has been shown to provide a means for axons to autonomously respond to guidance cues and injury (Willis and Twiss, 2006). Studies showing altered translation in axons have either not provided any analyses of which proteins are locally generated or have focused on single proteins (Wu et al., 2003; Piper and Holt, 2004; Wu et al., 2005; Leung et al., 2006; Piper et al., 2006; Yao et al., 2006). In the present study, we show that both growth-promoting and growth-inhibiting stimuli can differentially localize mRNAs to points of ligand stimulation.

The specificity in these mRNA localization responses is exhibited at multiple levels, including differential responses to growth-promoting versus growth-inhibiting ligands, differential responses to individual growth-promoting ligands, and even differences within downstream signaling pathways for responses to an individual ligand. The microtubule-dependent changes in axonal mRNA levels were reflected by a reciprocal decrease or increase in cell body mRNA content, suggesting a ligand-dependent alteration in delivery of mRNAs from the cell body. However, our data do not completely exclude the possibility that localized mRNA stability may also contribute to axonal mRNA content. Likewise, it is possible that both mRNA transport and stability are affected by distinct signaling pathways. Regardless of the specific mechanism, our findings indicate that extracellular signals can change the local concentrations of axonal mRNAs, which likely provides unique specificity to the localized protein synthetic responses.

Modulation of axonal mRNA levels is ligand specific

Although neurotrophins have been shown to increase the axonal localization of β-actin mRNA and local application of NGF and BDNF increases axonal levels of peripherin and vimentin mRNAs (Zhang et al., 1999, 2001; Willis et al., 2005), it has not been clear whether the neurotrophins or other ligands can decrease the axonal localization of any mRNAs. By analyzing the axonal levels of a large panel of mRNAs, our study shows that the axonal localization of individual mRNAs can be specifically increased or decreased in response to different ligands. A localized redistribution of mRNAs within the axons could contribute to the focal depletion of mRNAs as well as the translation product of localized eGFP<sup>SLmCherry</sup>β-actin mRNA adjacent to stimuli. With recent observations of the asymmetric redistribution of mRNA within growth cones in response to ligands (Leung et al., 2006; Yao et al., 2006) and the known short-range and bidirectional movements of RNA-binding proteins within RNA processes (Kiebler and Bassell, 2006), it is tempting to speculate that retrograde movement of mRNAs may also contribute to the decreased axonal mRNA levels seen in the quantitative experiments used here. Thus, although the reverse transcription qPCR approach has given us a unique view of dynamic ligand-dependent changes in total axonal mRNA levels, further studies will be needed to fully dissect the contributions of mRNA degradation and retrograde movement within axons for determining localized mRNA levels.

Surprisingly, even when ligands induce similar trophic responses, as with the individual neurotrophins, particular mRNAs can be uniquely affected. NGF and BDNF showed overall similar changes in levels of individual axonal mRNAs, but the response to NT3 appeared distinct. It is intriguing to speculate that differences in RNA transport reflect effects of these neurotrophins acting upon different neuronal subpopulations in the DRG (Snider, 1994). The ubiquitous expression of some mRNAs tested here (e.g., ribosomal proteins L22, L24, and S17; Amalidi et al., 1989; Kaspar et al., 1993) argues that these transcripts should also be available for regulation in the NT3-responsive DRG neurons. The extensive overlap between NGF, BDNF, and NT3 signal transduction (Segal, 2003) suggests that mRNA localization is matched to the specific ligand rather the overall trophic or tropic response to that ligand. Despite this overlap, tropic responses to neurotrophins can be distinct because cAMP can modify turning responses to NGF and BDNF, whereas cyclic guanosine monophosphate can modify turning responses to NT3 (Song and Poo, 1999). However, even with the similarities between NGF and BDNF, axonal levels of GAP-43 mRNA were uniquely altered by NGF. Because GAP-43 is expressed by all DRG neurons in the injury-conditioned cultures that were used here (Chong et al., 1994; Smith and Skene, 1997), GAP-43 mRNA should certainly be available for regulation in the BDNF-responsive neurons.

Ligand-specific effects were not limited to growth-promoting stimuli because DRG cultures treated with Sema3A and MAG also showed altered levels of individual mRNAs in the axons. Both the semaphorins and myelin inhibitors cause growth cone retraction in DRG neurons (Tanlian et al., 1997; Tang et al., 2001). For all but one of the 50 transcripts tested (vimentin), Sema3A and MAG modulated the localization of different mRNAs or generated the opposite response for individual mRNAs when compared with the neurotrophins. This supports the concept that axonal mRNA localization is tightly regulated with peripheral stimuli uniquely targeting individual mRNAs for focal increase or decrease along the axon.

Signal transduction pathways regulating axonal mRNA localization

Analyses of intracellular signaling showed further evidence of specificity for axonal mRNA localization mechanisms. Activation of Src family tyrosine kinases and Cdk5 by Sema3A increases rates of retrograde and anterograde vesicular transport even in isolated axons, but it is not clear what cargo is being transported in response to Sema3A (Sasaki et al., 2002; Li et al., 2004). Our data suggest that the local Sema3A stimulation of axons can direct the anterograde transport of cargo that includes mRNAs. The Sema3A-induced changes in axonal mRNA levels were sensitive to inhibition of Src family tyrosine kinases and Cdk5 (unpublished data), which is similar to what has been demonstrated for Sema3A-dependent vesicular transport (Sasaki et al., 2002; Li et al., 2004).

The neurotrophin-dependent alterations in mRNA localization reported here are Trk dependent for both the positively and negatively regulated mRNAs. For NGF, accumulation of the GFP reporter mRNA required retrograde transport. Although Trk activation is an obligate step in initiating retrograde signaling, there has been some debate about whether Trk is internalized and whether the retrogradely transported Trk includes ligand (Campenot and MacInnis, 2004; Zweifel et al., 2005). Our data do not distinguish whether Trk internalization is required for
Targeting mRNAs for axonal transport

The cDNA array analyses for identification of axonal transcripts show that >200 individual mRNAs can extend into these mammalian DRG processes. It is obvious that not all neuronal mRNAs extend into the axonal compartment of the cultured DRG neurons used here. This implies that the neuron somehow knows which mRNAs to target for localization into these processes. For rat β-actin mRNA, the 3′ UTR containing the rat zipcode element is sufficient to target a heterologous mRNA into adult DRG axons, similar to what has been demonstrated in other cell types (Hill et al., 1994; Kislauksis et al., 1994; Ross et al., 1997; Zhang et al., 1999; Farina et al., 2003). The other axonal mRNAs analyzed here likely contain localization elements, but their 3′ UTRs do not show any clear primary sequence homology to the β-actin zipcode (unpublished data). Interestingly, our data indicate that the DRG neurons not only know where to target mRNAs but also can be specifically instructed where not to send individual mRNAs within the axon. The localization of mRNAs to focal sites of ligand stimulation is quite similar to dendritic mRNA localization, in which activated postsynaptic regions are tagged for RNA delivery (Steward et al., 1998; Steward and Halpain, 1999; Aakalu et al., 2001; Tongiorgi et al., 2004).

Several lines of evidence indicate that localized mRNAs are also translationally regulated. Huttelmaier et al. (2005) showed that Src-dependent phosphorylation releases the zipcode binding protein from β-actin’s zipcode element, allowing translational activation of the mRNA. Because microtubule depolymerization completely blocked neurotrophin-dependent increase in β-actin mRNA by qPCR and prevented the localization of GFP<sub>NLS+myr</sub> β-actin in response to NGF, our studies suggest that localization of the encoding mRNA provides a key means to regulate axonal expression of this protein in DRG neurons. Our data do not preclude the possibility that the translation of axonal mRNAs is also tightly regulated by extracellular stimuli. This may indeed be the case for the majority of mRNAs with constitutive axonal localization.

Verma et al. (2005) reported that the ability to regenerate axons correlates with the protein synthetic capacity of the axon. Our analyses of growth-promoting and growth-inhibiting ligands suggest that the synthetic capacity of growing axons is directly regulated by extracellular stimuli. The distinct effects of the neurotrophins versus MAG and Sema3A may point to antagonistic effects of these growth-promoting and growth-inhibiting stimuli on axonal mRNA levels. The growth-inhibitory effects of MAG can be overcome by priming neurons with neurotrophins or agents that increase cAMP levels (Cai et al., 1999, 2001; Lu et al., 2004). Our data clearly show that growth-inhibiting stimuli from the central nervous system can regulate axonal mRNA localization and that these effects can be mitigated by offering the neuron antagonizing stimuli. Because MAG is a known growth inhibitory molecule in central nervous system white matter (Filbin, 2003), this raises the intriguing possibility that alterations in mRNA localization may accompany the failed regeneration of central nervous system axons. Our identification of the positive roles of neurotrophins in stimulating mRNA localization in these regenerating adult sensory neurons in vitro should provide motivation to investigate a role for similar pathways in vivo. For example, TrkB signaling can enhance axonal regeneration in vivo (English et al., 2005), and this may depend, in part, on regulated mRNA localization and localized protein synthesis in regenerating sensory and motor nerves. The effect of MAG for focal depletion of axonal β-actin mRNA did not require retrograde transport; thus, trophic stimuli that can signal the cell body to modulate axonal mRNA levels may be able to overcome the local inhibitory effects of MAG on axonal protein synthesis.

Materials and methods

Pharmacological reagents

NGF (Harlan), BDNF, NT3 (Alomone Labs), MAG-Fc (R&D Systems), and Sema3A-AP (Nakajima et al., 2006) were covalently coupled to 15-μm-diameter polystyrene microparticles according to the manufacturer’s instructions (Polysciences). The following control proteins were also immobilized onto polystyrene microparticles or particles: BSA (Sigma-Aldrich) for NGF, BDNF, and NT3; human IgG-Fc (R&D Systems) for MAG-Fc; and AP for Sema3A-AP (provided by Y. Goshima, Yokohama University, Yokohama, Japan; Nakajima et al., 2006). Efficiency of absorption was determined by Bradford assay for unbound protein. To determine the mechanisms involved in modulation of axonal mRNA transport, DRG cultures were treated with the following pharmacological agents 30 min before the addition of immobilized ligands: 200 nM K252A (Calbiochem), 50 μM PD98059 (Biomol), 50 μM LY294002 (Biomol), 10 μM Lavendustin (Biomol), 10 μM Olomoucine (Biomol), 1 mM db-cAMP (Sigma-Aldrich), 10 μg/ml cycloheximide (Sigma-Aldrich), 10 μM cytochalasin D (Sigma-Aldrich), and 1 μg/ml colchicine (Sigma-Aldrich). 50 nM EHNA (Sigma-Aldrich) was added to cultures 3 h before use.

Cell culture and axonal isolations

All animal surgeries and euthanasiad were performed according to institutional Animal Care and Use Committee guidelines under approved protocols. Primary DRG cultures were prepared from Sprague Dawley rats that had been injury conditioned 7 d before by sciatic nerve crush at midthigh level (Smith and Skene, 1997). Dissociated cultures were prepared from...
L4-L5 DRGs as previously described (Twiss et al., 2000). Cultures were plated at moderate density on membrane inserts (for axonal isolation, see next paragraph) or at low density on coverslips (for live cell imaging and FISH analyses, see respective sections below).

The culture method for isolating DRG axons from cell bodies and nonneuronal cells has been previously described (Zheng et al., 2001; Willis et al., 2005). In brief, dissociated DRGs were plated into tissue culture inserts containing porous membranes (8-μm-diameter pores; BD Falcon), which were coated with poly-lysine (Sigma-Aldrich) and laminin (Upstate Biotechnology). Axons were isolated after 16–20 h in culture by scraping away the cellular content from the upper or lower membrane surfaces (yielding axonal or cell body preparations, respectively). The purity of the axonal preparations was tested by RTPCR for microtubule-associated protein 2, γ-actin, and β-actin mRNAs.

cDNA array analyses
Axonal RNA was isolated as described in the previous section, and the purity was confirmed by RTPCR for β-actin, γ-actin, and microtubule-associated protein 2 (Fig. S1 A). 200 ng was used as a template for RT-PCR purification was confirmed by RT-PCR for microtubule-associated protein 2 (Fig. S1 A). 200 ng was used as a template for RT-PCR using the SMART PCR cDNA Synthesis kit (CLONTECH Laboratories, Inc.) for γ-actin and microtubule-associated protein 2 (Fig. S1 A). 200 ng was used as a template for RT-PCR using the SMART PCR cDNA Synthesis kit (CLONTECH Laboratories, Inc.) to generate full-length double-stranded cDNA. Aliquots of the amplification were removed from the PCR every third cycle from 12–30 cycles and used for Southern blotting. Southern blots were probed with 32P-labeled β-actin cDNA to test for linearity (Fig. S1 B). The aliquot below where linearity was lost was used to generate a 32P-labeled probe cDNA using the Advantage 2 PCR System (CLONTECH Laboratories, Inc.) and hybridized to Atlas Plastic Rat 4K Microarrays (CLONTECH Laboratories, Inc.). Hybridization signals were detected by phosphorimaging, and results were analyzed using Atlas Image 2.7 software (CLONTECH Laboratories, Inc.). For comparison between arrays, individual hits were normalized across the individual array and assigned a relative intensity.

Localized treatment of axons
The culture method for treatment of intact DRG axons has been previously described (Willis et al., 2005). In brief, DRGs were cultured on a porous membrane in the presence of 80 μM of the RNA synthesis inhibitor DRB throughout the culture period (Sigma-Aldrich). After 16–20 h in culture, the axonal compartment was separately exposed to the protein-coupled microparticles by placing the inserts into dishes with shallower wells in which the bottom surface of the insert directly contacted coated microparticles along the bottom of the wells. Microparticles of 15 μm diameter were used for these stimulations to restrict any passage through the 8-μm pores of the membrane, which limited stimulation to the axonal compartment. After 4 h of treatment, membranes were rinsed in PBS, and the axonal compartment was isolated as described in Cell culture and axonal isolations. RNA was extracted from the fractionated cultures using the RNAqueous Micro kit (Ambion) and quantified using fluorometry with the NanoOrange reagent (Ambion). The reverse transcription reactions were diluted each) were used as a template for reverse transcription using the iScript RT System (Bio-Rad Laboratories). The reverse transcription reactions were diluted and antisense γ-actin (5′-AAGGAAA-AAAAGCGGCGCGCCGACTGTTTAGCCTGCAG-3′), sense β-actin (5′-TCTATCGGATTTACCTGTCACGGCAG-3′), sense γ-actin (5′-AAG-AAAAGCGGCGCGCCGACTGTTTAGCCTGCAG-3′), and antisense γ-actin (5′-TCTATCGGATTTACCTGTCACGGCAG-3′) PCR products were cloned into pTOPO vector (Invitrogen) and sequenced. Sequences were compared with γ-actin and β-actin 3′ UTRs published in Cell culture and axonal isolations.

To visualize the localized effects of immobilized ligand exposure to axons, 4.5-μm microparticles were used. For live cell imaging (see Live cell imaging section below), fluorescent microparticles were added to cultures growing on poly-lysine/laminin chambered coverslips. For the FISH studies (see FISH section below), 7-d injury-conditioned DRGs were cultured overnight in the presence of carboxylated polylysylne microparticles with immobilized neurotransphins, MAG, or Sema3A. In these experiments, the ligand-immobilized microparticles were coupled directly to the laminin surface, which prevented them from being washed away in subsequent FISH/imunofluorescence steps. For this, ligands were coupled to microparticles overnight according to the manufacturer’s protocol (Polysciences). Microparticles were then added to the coated coverslips for 4 h. Unreacted sites were blocked with ethanolamine, and coverslips were washed and used for standard DRG culture.

Analysis of axonal RNAs
For analyses of axonal transcripts, normalized axonal RNAs (~50 ng each) were used as a template for reverse transcription using the iScript RT kit (Bio-Rad Laboratories). The reverse transcription reactions were diluted 10-fold, and the purity of each axonal preparation was assessed by RTPCR for γ-actin and microtubule-associated protein 2 mRNAs, which are expressed at high levels in rat DRG cultures but are excluded from the axonal compartment as previously described (Willis et al., 2005). Validated axonal RNA preparations were then used for reverse transcription qPCR.

In brief, reverse-transcribed axonal RNA was amplified using the Prism 7900HT sequence detection system (Applied Biosystems) with 2× SybrGreen Master Mix (QIAGEN) according to the manufacturer’s standard cycling parameters. Rat brain RNA was used as a template to generate standard curves for all primer pairs. A robotic system (Biomek 2000; Beckman Coulter) was used to standardize the pipetting of samples and reagents into 384-well plates for qPCR. All samples were assayed in quadruplicate from at least three independent experiments each. In addition to controlling for axonal number based on protein content, the relative levels of each transcript were normalized to the 125 mitochondrial ribosomal RNA control by the comparative threshold method (CT) to provide an internal control for reverse transcription efficiency and axonal content. RNA values are expressed relative to control (BSA for NGF, BDNF, and NT3 treatments; Fc for MAG-FC treatment; and AP for Sema3A treatment).

Metabolic labeling of RNA
Injury-conditioned DRGs were cultured overnight ± 80 μM DRB. Culture medium was then supplemented with 125 μCi/ml α-[33P]UTP (GE Healthcare). After a 4-h labeling period, total RNA was extracted and quantified by fluorometry as described in Localized treatment of axons. The specific activity was determined by liquid scintillation counting. These labeled RNA samples (2 μg each) were electrophoresed in a 6% acrylamide gel. After electrophoresis, the gel was stained with ethidium bromide, imaged under UV to verify RNA loading and integrity, and dried, and used for autoradiography.

cDNA constructs for expressing chimeric mRNAs
Chimeric reporter cDNA constructs were generated by replacing the 3′ UTR of the aCamKII-eGFPNLS/myr constructs (provided by E. Schuman, California Institute of Technology, Pasadena, CA; Akakli et al., 2001) with that of the rat γ-actin and β-actin mRNAs. cDNA encoding 3′ UTRs of these rat mRNAs were isolated by RTPCR from rat brain RNA template using the following primers engineered with NotI and XhoI restriction sites (actin components are underlined): sense β-actin (5′-AAGGAAA-AAAAGCGGCGCGCCGACTGTTTAGCCTGCAG-3′), antisense β-actin (5′-TCTATCGGATTTACCTGTCACGGCAG-3′), sense γ-actin (5′-AAG-AAAAGCGGCGCGCCGACTGTTTAGCCTGCAG-3′), and antisense γ-actin (5′-TCTATCGGATTTACCTGTCACGGCAG-3′). After digestion with NotI and XhoI, these constructs were ligated into pMSCV/Neo plasmid (Invitrogen) and sequenced. Sequences were compared with γ-actin and β-actin 3′ UTRs published in Cell culture and axonal isolations. The specific activity was determined by liquid scintillation counting. These labeled RNA samples (2 μg each) were electrophoresed in a 6% acrylamide gel. After electrophoresis, the gel was stained with ethidium bromide, imaged under UV to verify RNA loading and integrity, and dried, and used for autoradiography.

dRNA constructs for expressing chimeric mRNAs
Chimeric reporter cDNA constructs were generated by replacing the 3′ UTR of the aCamKII-eGFPNLS/myr constructs (provided by E. Schuman, California Institute of Technology, Pasadena, CA; Akakli et al., 2001) with that of the rat γ-actin and β-actin mRNAs. cDNA encoding 3′ UTRs of these rat mRNAs were isolated by RTPCR from rat brain RNA template using the following primers engineered with NotI and XhoI restriction sites (actin components are underlined): sense β-actin (5′-AAGGAAA-AAAAGCGGCGCGCCGACTGTTTAGCCTGCAG-3′), antisense β-actin (5′-TCTATCGGATTTACCTGTCACGGCAG-3′), sense γ-actin (5′-AAG-AAAAGCGGCGCGCCGACTGTTTAGCCTGCAG-3′), and antisense γ-actin (5′-TCTATCGGATTTACCTGTCACGGCAG-3′). After digestion with NotI and XhoI, these constructs were ligated into pMSCV/Neo plasmid (Invitrogen) and sequenced. Sequences were compared with γ-actin and β-actin 3′ UTRs published in Cell culture and axonal isolations. The specific activity was determined by liquid scintillation counting. These labeled RNA samples (2 μg each) were electrophoresed in a 6% acrylamide gel. After electrophoresis, the gel was stained with ethidium bromide, imaged under UV to verify RNA loading and integrity, and dried, and used for autoradiography.

siRNA transfection
Dynein-based transport was diminished using ON-TARGET Plus SMARTpool siRNA targeting Dyn1c1h1 (GenBank/EMBL/DDB accession no. NM_019226; Dharmaco) or siGLO-Red reagent (Dharmacon) was used for identifying transfected neurons in the live cell imaging experiments (see Live cell imaging section below). After 12 h in vitro, DRG cultures were transfected with siRNAs using DharmatactFECT3 as per the manufacturer’s instructions (Dharmacon). The cultures were exposed to 50 nM of total siRNA (25 nM Dyn1c1h1 and 25 nM siGLO-Red) plus 1.0 μM DharmatactFECT3 in a total culture volume of 1 ml. After 24 h, the culture medium was replaced, and the cells were allowed to grow for 72 h. For this, control and siRNA-treated cultures were lysed in radioimmuno-precipitation assay buffer (0.1% SDS, 50 mM TrisCl, pH 6.8, 150 mM NaCl, 0.5% NP-40, and 2 mM EDTA), cleared by centrifugation, and normalized for protein content by Bradford assay (Bio-Rad Laboratories). lysate were denatured, fractionated by SDS/PAGE, and transferred to polyvinylidene
dilute RNAse [Willis et al., 2005]. Blots were blocked in Tris-buff-
ered saline with 0.1% Tween 20 (TBST) plus 5% nonfat dry milk for 1 h and then incubated overnight at 4°C in rabbit anti-dynein HC antibody (1:200; Santa Cruz Biotechnology, Inc.). Blots were rinsed several times in TBST and incubated with HRP-conjugated anti-rabbit IgG (1:5,000; Cell Signal-
ing) for 1 h at room temperature. Blots were washed for 30 min in TBST and developed with ECL (GE Healthcare).

Live cell imaging

NF-coated and/or MAG-coated Fluresbrite YO Carboxylate Micro-
ospheres (4.5 or 6.0 μm; Polysciences) were added to cultures of infected DRGs at a low density and allowed to settle for 20 min before imaging. GFP-expressing neurons that contacted a fluorescent probe-bound micro-
particle were imaged by confocal microscopy using an inverted laser-
scanning system (TCS/SP2 LSM; Leica) on an inverted microscope (DMIRE2; Leica) fitted with an environmental chamber to maintain a humidified temperature of 37°C with 5% CO2. A 63× NA 1.4 oil immersion objective (Leica) was used for all imaging. The pinhole was set for 5 airy U to allow the acquisition of emission over the full thickness of the axon. The objective (Leica) was used for all imaging. The pinhole was set for 5 airy U to allow the acquisition of emission over the full thickness of the axon. This work was supported by grants from the NIH (NS041696 and NS040941 to J.L. Twiss and HD46368 to G.J. Bassell), the Dr. Miriam and Sheldon G. Adelson Medical Research Foundation, and programmatic fund-
ing from the Nemours Foundation. D.E. Willis is supported by a Ruth Kirschstein National Research Service Award (grant NS047821). All quantitative measurements were performed on the original 16-bit images using ImageJ [NIH]. The point of the axon corresponding to the center of the particle was used as a reference point for measuring pixel intensity of the Cy3 emission. A 5-μm segment of axon corresponding to 2.5 μm proximal and distal to the particle center was used as the zero point. From this, the pixels/micrometer2 was divided by a mean in three bins proximal to and distal to the particle center (5-μm length each plus 5-μm bin at particle center). Back-
ground was subtracted from the intensity values, and subtracted signal inten-
sity in each 5-μm bin was normalized to the mean intensity over the entire 35-μm axon region that was measured.

Online supplemental material

Table S1 shows array-based identification of axonal mRNAs with the mean intensity of four axonal RNA preparations. Fig. S1 shows the purity of the axonal RNA used to generate the cDNA to probe the arrays (A) and confirms the linear amplification of the cDNA by virtual Northern blotting (B). Fig. S2 shows the expression of sP[UTP] labeling of DRG cultures ± DB to confirm the ef-
efectiveness of RNA polymerase II inhibition (A) and presents a Western blot confirming the reduced levels of dynein heavy chain in DRGs treated with the Dnc1h1 siRNA for 72 h (B). Fig. S3 shows cultured DRGs infected with either eGFPNLS/myr-actin 3’ UTR or eGFPNLS/myr-actin 3’ UTR reporter constructs. Fig. S4 shows the cultured DRG response to immobilized sources of NGF (A), BSA (B), MAG-Fc (C), or IgG-Fc (D). The figure also shows that pretreatment with K252A before the addition of immobilized NGF shows a requirement for TrkA signaling (C) and that pretreatment with db-cAMP before addition of MAG-Fc shows a reversal of MAG's effects by elevation of cAMP signaling (F). Video 1 shows live cell imaging of a neuron exposed to immobilized NGF (video of cell shown in Fig. 5 A). Video 2 shows a neuron pretreated with PD98059 before NGF exposure (video of cell shown in Fig. 5 B). Video 3 shows a DRG treated with colchicine before NGF exposure (video of cell shown in Fig. 5 C). Video 4 shows a neuron transfected with DynCharts siRNA and stained with Lys-
Tracker to show reduced retrograde but not anterograde transport. Video 5 shows a neuron treated with the dynein inhibitor ETHA and stained with Lys-
Tracker to show reduced retrograde movement. Video 5 shows a neuron exposed to immobilized MAG-Fc (video of cell shown in Fig. 6 A). Video 7 shows a neuron treated with db-cAMP before exposure to immobilized MAG-Fc (video of cell shown in Fig. 6 C).
