Abstract

In many robotic applications the need to represent and reason about spatial uncertainty is of great importance. However, our knowledge of particular spatial relationships is inherently uncertain. The most used method for handling the uncertainty is to "pre-engineer" the problem away, by structuring the working environment and using specially-suited high-precision equipment. In some advanced robotic research domains, however, such as automatic task planning, off-line robot programming, and autonomous vehicle operation, prior structuring will not be possible, because of dynamically changing environments, or because of the demand for greater reasoning flexibility. Spatial reasoning is further complicated because relationships are often not described explicitly, but are given by uncertain relative information. This is particularly true when many different frames of reference are used, producing a network of uncertain relationships. Rather than treat spatial uncertainty as a side issue in geometrical reasoning, we believe it must be an intrinsic part of spatial representations. In this paper, we describe a representation for spatial information, called the stochastic map, and associated procedures for building it, reading information from it, and revising it incrementally as new information is obtained. The map always contains the best estimates of relationships among objects in the map, and their uncertainties. The procedures provide a general solution to the problem of estimating uncertain relative spatial relationships. The estimates are probabilistic in nature, an advance over the previous, very conservative, worst-case approaches to the problem. Finally, the procedures are developed in the context of state-estimation and filtering theory, which provides a solid basis for numerous extensions.

1 Introduction

In many applications of robotics, such as industrial automation, and autonomous vehicles, there is a need to represent and reason about spatial uncertainty. In the past, this need has been circumvented by special purpose methods such as precision engineering, very accurate sensors and the use of fixtures and calibration points. While these methods sometimes supply sufficient accuracy to avoid the need to represent uncertainty explicitly, they are usually costly. An alternative approach is to use multiple, overlapping, lower resolution sensors and to combine the spatial information (including the uncertainty) from all sources to obtain the best spatial estimate. This integrated information can often supply sufficient accuracy to avoid the need for the hard engineered approach.

In addition to lower hardware cost, the explicit
estimation of uncertain spatial information makes it possible to decide in advance whether proposed operations are likely to fail because of accumulated uncertainty, and whether proposed sensor information will be sufficient to reduce the uncertainty to tolerable limits. In other situations, such as inexpensive mobile robots, the only way to obtain sufficient accuracy is to combine the (uncertain) information from many sensors.

A difficulty in combining uncertain spatial information is that it often occurs in the form of uncertain relative information. This is particularly true where many different frames of reference are used, and the uncertain spatial information must be propagated between these frames. This paper presents a general solution to the problem of estimating uncertain spatial relationships, regardless of which frame the information is presented in, or in which frame the answer is required. The basic theory assumes that the errors are "small", so that the nonlinear transformations from one frame to another are approximately linear.

Early methods for representing spatial uncertainty (e.g. [Taylor, 1976]) numerically computed min-max bounds on errors in typical robotics applications. Brooks extended this analysis to symbolically computing min-max bounds [Brooks, 1982]. This min-max approach is very conservative compared to the probabilistic approach in this paper, because it always assumes the worst case when combining information. More recently, a probabilistic representation of uncertainty was developed for the HILARE robot [Chatila, 1985] that is similar to the method presented here, except that it uses only a scalar representation of positional uncertainty instead of a multivariate one. In a recent paper, Brooks developed a representation of spatial uncertainty based on bounding cylinders and a combining operation based on the intersections of such cylinders [Brooks, 1985]. Smith and Cheeseman ([Smith, 1984], [Smith, 1985]), working on problems in off-line programming of industrial automation tasks, proposed operations that could reduce graphs of uncertain relationships (represented by multivariate probability distributions) to a single, best estimate of some relationship of interest. The current paper extends that work, but in the formal setting of estimation theory, and does not utilize graph transformations.

In summary, many important applications require a representation of spatial uncertainty. In addition, methods for combining uncertain spatial information and transforming such information from one frame to another are required. This paper presents a matrix representation of spatial uncertainty that explicitly represents the uncertainty for each degree of freedom in the world of interest. A method is given for combining uncertain information regardless of which frame it is presented in, and it allows the description of the spatial uncertainty of one frame relative to any other frame. The necessary procedures are presented in matrix form, suitable for efficient implementation. In particular, methods are given for incrementally building the best estimate "map" and its uncertainty as new pieces of uncertain spatial information are added.

2 The Stochastic Map

Our knowledge of the spatial relationships among objects is inherently uncertain. A man-made object does not match its geometric model exactly because of manufacturing tolerances. Even if it did, a sensor could not measure the geometric features, and thus locate the object exactly, because of measurement errors. And even if it could, a robot using the sensor cannot manipulate the object exactly as intended, because of hand positioning errors. These errors can be reduced to negligible limits for some tasks, by "pre-engineering" the solution — structuring the working environment and using specially-suitcd high-precision equipment — but at great cost of time and expense.

However, rather than treat spatial uncertainty as a side issue in geometrical reasoning, we believe it must be treated as an intrinsic part of spatial representations.

In this paper, uncertain spatial relationships will be tied together in a representation called the stochastic map. It contains estimates of the spatial relationships, their uncertainties, and their interdependencies.

First, the map structure will be described, followed by methods for extracting information from
it. Finally, a procedure will be given for building the map incrementally, as new spatial information is obtained.

To illustrate the theory, we will present an example of a mobile robot acquiring knowledge about its location and the organization of its environment by making sensor observations at different times and in different places.

2.1 Representation

In order to formalize the above ideas, we will define the following terms. A spatial relationship will be represented by the vector of its spatial variables, \( \mathbf{x} \). For example, the position and orientation of a mobile robot can be described by its coordinates, \( x \) and \( y \), in a two dimensional cartesian reference frame and by its orientation, \( \phi \), given as a rotation about the \( z \) axis:

\[
\mathbf{x} = \begin{bmatrix} x \\ y \\ \phi \end{bmatrix}.
\]

An uncertain spatial relationship, moreover, can be represented by a probability distribution over its spatial variables — i.e., by a probability density function that assigns a probability to each particular combination of the spatial variables, \( \mathbf{x} \):

\[
P(\mathbf{x}) = f(\mathbf{x})d\mathbf{x}.
\]

Such detailed knowledge of the probability distribution is usually unnecessary for making decisions, such as whether the robot will be able to complete a given task (e.g. passing through a doorway). Furthermore, most measuring devices provide only a nominal value of the measured relationship, and we can estimate the average error from the sensor specifications. For these reasons, we choose to model an uncertain spatial relationship by estimating the first two moments of its probability distribution — the mean, \( \bar{x} \) and the covariance, \( \mathbf{C}(\mathbf{x}) \), defined as:

\[
\bar{x} \triangleq E(\mathbf{x}),
\]

\[
\hat{x} \triangleq \mathbf{x} - \bar{x},
\]

\[
\mathbf{C}(\mathbf{x}) \triangleq E(\hat{x}\hat{x}^T).
\]

where \( E \) is the expectation operator, and \( \hat{x} \) is the deviation from the mean.

For our mobile robot example, these are:

\[
\hat{x} = \begin{bmatrix} \hat{x}_x \\ \hat{x}_y \\ \hat{x}_\phi \end{bmatrix}, \quad \mathbf{C}(\mathbf{x}) = \begin{bmatrix} \sigma_x^2 & \sigma_{xy} & \sigma_{x\phi} \\ \sigma_{xy} & \sigma_y^2 & \sigma_{y\phi} \\ \sigma_{x\phi} & \sigma_{y\phi} & \sigma_\phi^2 \end{bmatrix}.
\]

Here, the diagonal elements of the covariance matrix are just the variances of the spatial variables, while the off-diagonal elements are the covariances between the spatial variables. It is useful to think of the covariances in terms of their correlation coefficients, \( \rho_{ij} \):

\[
\rho_{ij} \triangleq \frac{\sigma_{ij}}{\sigma_i \sigma_j} = \frac{E(\hat{x}_i \hat{x}_j)}{\sqrt{E(\hat{x}_i^2)E(\hat{x}_j^2)}}, \quad -1 \leq \rho_{ij} \leq 1.
\]

Similarly, to model a system of \( n \) uncertain spatial relationships, we construct the vector of all the spatial variables, which we call the system state vector. As before, we will estimate the mean of the state vector, \( \bar{x} \), and the system covariance matrix, \( \mathbf{C}(\mathbf{x}) \):

\[
x = \begin{bmatrix} x_1 \\ x_2 \\ \vdots \\ x_n \end{bmatrix}, \quad \bar{x} = \begin{bmatrix} \bar{x}_1 \\ \bar{x}_2 \\ \vdots \\ \bar{x}_n \end{bmatrix}, \quad \mathbf{C}(\mathbf{x}) = \begin{bmatrix} C(x_1) & C(x_1, x_2) & \cdots & C(x_1, x_n) \\ C(x_2, x_1) & C(x_2) & \cdots & C(x_2, x_n) \\ \vdots & \vdots & \ddots & \vdots \\ C(x_n, x_1) & C(x_n, x_2) & \cdots & C(x_n) \end{bmatrix}
\]

where:

\[
C(x_i, x_j) \triangleq E(\hat{x}_i \hat{x}_j^T), \quad C(x_i, x_i) = E(\hat{x}_i^2).
\]

Here, the \( x_i \)'s are the vectors of the spatial variables of the individual uncertain spatial relationships, and the \( C(x_i) \)'s are the associated covariance matrices, as discussed earlier. The \( C(x_i, x_j) \)'s
are the cross-covariance matrices between the uncertain spatial relationships, which allow for dependencies between the uncertainties of different spatial relationships. These off-diagonal matrices provide the mechanism for back-propagating new information added to the map, in order to improve previous spatial estimates, and are significantly more sophisticated than previous methods for doing this.

In our example, each uncertain spatial relationship is of the same form, so \( \mathbf{x} \) has \( m = 3n \) elements, and we may write:

\[
\mathbf{x}_i = \begin{bmatrix} x_i \\ y_i \\ \phi_i \end{bmatrix}, \quad \mathbf{\hat{x}}_i = \begin{bmatrix} \hat{x}_i \\ \hat{y}_i \\ \hat{\phi}_i \end{bmatrix},
\]

\[
\mathbf{C}(\mathbf{x}_i, \mathbf{x}_j) = \begin{bmatrix} \sigma_{x_ix_j} & \sigma_{x_iy_j} & \sigma_{x_i\phi_j} \\ \sigma_{y_ix_j} & \sigma_{y_iy_j} & \sigma_{y_i\phi_j} \\ \sigma_{\phi_ix_j} & \sigma_{\phi_iy_j} & \sigma_{\phi_i\phi_j} \end{bmatrix}.
\]

Thus our "map" consists of the current estimate of the mean of the system state vector, which gives the nominal locations of objects in the map with respect to the world reference frame, and the associated system covariance matrix, which gives the uncertainty of each point in the map and the interdependencies of these uncertainties.

### 2.2 Interpretation

For some decisions based on uncertain spatial relationships, we must assume a particular distribution that fits the estimated moments. For example, a robot might need to be able to calculate the probability that a certain object will be in its field of view, or the probability that it will succeed in passing through a doorway.

Given only the mean, \( \mathbf{x} \), and covariance matrix, \( \mathbf{C}(\mathbf{x}) \), of a multivariate probability distribution, the principle of maximum entropy indicates that the distribution which assumes the least information is the normal distribution. Furthermore if the spatial relationship is calculated by combining evidence from many independent observations, the central limit theorem indicates that the resulting distribution will tend to a normal distribution:

\[
P(\mathbf{x}) = \frac{\exp \left[-\frac{1}{2}(\mathbf{x} - \mathbf{x})^T \mathbf{C}^{-1}(\mathbf{x})(\mathbf{x} - \mathbf{x})\right]}{\sqrt{(2\pi)^m |\mathbf{C}(\mathbf{x})|}} \ dx. \quad (4)
\]

We will graph uncertain spatial relationships by plotting contours of constant probability from a normal distribution with the given mean and covariance information. These contours turn out to be concentric ellipsoids (ellipses for two dimensions) whose parameters can be calculated from the covariance matrix, \( \mathbf{C}(\mathbf{x}_i) \) [Nahi, 1976]. It is important to emphasize that we do not assume that the uncertain spatial relationships are described by normal distributions. We estimate the mean and variance of their distributions, and use the normal distribution only when we need to calculate specific probability contours.

In the figures in this paper, the plotted points show the actual locations of objects, which are known only by the simulator and displayed for our benefit. The robot's information is shown by the ellipses which are drawn centered on the estimated mean of the relationship and such that they enclose a 99.9% confidence region (about four standard deviations) for the relationships.

### 2.3 Example

Throughout this paper we will refer to a two-dimensional example involving the navigation of a mobile robot with three degrees of freedom. In this example the robot performs the following sequence of actions:

- The robot senses object #1.
- The robot moves.
- The robot senses an object (object #2) which it determines cannot be object #1.
- Trying again, the robot succeeds in sensing object #1, thus helping to localize itself, object #1, and object #2.
Figure 1 shows two examples of uncertain spatial relationships — the sensed location of object #1, and the end-point of a planned motion for the robot. The robot is initially sitting at the location marked 'O'. There is enough information in our stochastic map at this point for the robot to be able to decide how likely a collision with the object is, if the motion is made. In this case the probability is vanishingly small.

Figure 2 shows how this spatial knowledge can be presented from the robot's new reference frame after its motion. As expected, the uncertainty in the location of object #1 becomes larger when it is compounded with the uncertainty in the robot's motion.

From this new location, the robot senses object #2 (Figure 3). The robot is able to determine with the information in its stochastic map that this must be a new object and is not object #1 which it observed earlier.

In figure 4, the robot senses object #1 again. This new, loop closing sensor measurement acts as a constraint, and is incorporated into the map, reducing the uncertainty in the locations of the robot, object #1 and Object #2 (Figure 5).

3 Reading the Map

3.1 Uncertain Relationships

Having seen how we can represent uncertain spatial relationships by estimates of the mean and covariance of the system state vector, we now discuss methods for estimating the first two moments of unknown multivariate probability distributions. See [Papoulis, 1965] for detailed justifications of the following topics.

3.1.1 Linear Relationships

The simplest case concerns relationships which are linear in the random variables, e.g.:

\[ y = Mx + b, \]

where, \( x \) \((n \times 1)\) is a random vector, \( M \) \((r \times n)\) is the non-random coefficient matrix, \( b \) \((r \times 1)\) is a constant vector, and \( y \) \((r \times 1)\) is the resultant random vector. Using the definitions from (1), and the linearity of the expectation operator, \( E \), one can easily verify that the mean of the relationship, \( \hat{y} \), is given by:

\[ \hat{y} = M\hat{x} + b, \]

and the covariance matrix, \( C(y) \), is:

\[ C(y) = MC(x)M^T. \]

We will also need to be able to compute the covariance between \( y \) and some other relationship, \( z \), given the covariance between \( x \) and \( z \):

\[ C(y, z) = MC(x, z), \]

\[ C(z, y) = C(z, x)M^T. \]
THE ROBOT SENSES OBJECT #2

Figure 3:

THE ROBOT SENSES OBJECT #1 AGAIN

Figure 4:

THE UPDATE FROM THE ROBOT'S FRAME

THE UPDATE FROM THE WORLD FRAME

Figure 5:
The first two moments of the multivariate distribution of \( y \) are computed exactly, given correct moments for \( x \). Further, if \( x \) follows a normal distribution, then so does \( y \).

### 3.1.2 Non-Linear Relationships

The first two moments computed by the formulae below for non-linear relationships on random variables will be first-order estimates of the true values. To compute the actual values requires knowledge of the complete probability density function of the spatial variables, which will not generally be available in our applications. The usual approach is to approximate the non-linear function

\[ y = f(x) \]

by a Taylor series expansion about the estimated mean, \( \bar{x} \), yielding:

\[ y = f(\bar{x}) + F_x \bar{x} + \cdots, \]

where \( F_x \) is the matrix of partials, or Jacobian, of \( f \) evaluated at \( \bar{x} \):

\[ F_x = \frac{\partial f(x)}{\partial x} \]

\[ \bar{x} = \begin{bmatrix} \frac{\partial f_1}{\partial x_1} & \frac{\partial f_1}{\partial x_2} & \cdots & \frac{\partial f_1}{\partial x_n} \\ \frac{\partial f_2}{\partial x_1} & \frac{\partial f_2}{\partial x_2} & \cdots & \frac{\partial f_2}{\partial x_n} \\ \vdots & \vdots & \ddots & \vdots \\ \frac{\partial f_n}{\partial x_1} & \frac{\partial f_n}{\partial x_2} & \cdots & \frac{\partial f_n}{\partial x_n} \end{bmatrix} \]

This terminology is the extension of the \( f_x \) terminology from scalar calculus to vectors. The Jacobians are always understood to be evaluated at the estimated mean of the input variables.

Truncating the expansion for \( y \) after the linear term, and taking the expectation produces the linear estimate of the mean of \( y \):

\[ \hat{y} \approx f(\bar{x}). \]

Similarly, the first-order estimate of the covariances are:

\[ C(y) \approx F_x C(x) F_x^T, \]

\[ C(y, z) \approx F_x C(x, z), \]

\[ C(z, y) \approx C(z, x) F_x^T. \]

Though not utilized in our application, the second order term may be included in the Taylor series expansion to improve the mean estimate:

\[ y = f(\bar{x}) + F_x \bar{x} + \frac{1}{2} F_{xx} (\bar{x} \bar{x}^T) + \cdots, \]

We denote the (3 dimensional) matrix of second partials of \( f \) by \( F_{xx} \). To avoid unnecessary complexity, we simply state that the \( th \) element of the vector produced when \( F_{xx} \) is multiplied on the right by a matrix \( A \) is defined by:

\[ (F_{xx} A)_t = \text{trace} \left[ \left( \frac{\partial^2 f_i}{\partial x_j \partial x_k} \right)_{x=x} A \right]. \]

The second-order estimate of the mean of \( y \) is then:

\[ \hat{y} \approx f(\bar{x}) + \frac{1}{2} F_{xx} C(x), \]

and the second-order estimate of the covariance is:

\[ C(y) \approx F_x C(x) F_x^T - \frac{1}{4} F_{xx} C(x) C(x)^T F_{xx}. \]

In the remainder of this paper we consider only first order estimates, and the symbol "\( \approx \)" should read as "linear estimate of."

### 3.2 Spatial Relationships

We now consider the actual spatial relationships which are most often encountered in robotics applications. We will develop our presentation about the three degree of freedom formulae, since they suit our examples concerning a mobile robot. Formulae for the three dimensional case with six degrees of freedom are given in Appendix A.

#### 3.2.1 Compounding

Given two spatial relationships, \( x_{ij} \) and \( x_{jk} \), as in Figure 2, we wish to compute the resultant relationship \( x_{ik} \). The formula for computing \( x_{ik} \) from \( x_{ij} \) and \( x_{jk} \) is:

\[ x_{ik} \define x_{ij} \odot x_{jk} \]

\[ = \begin{bmatrix} x_{jk} \cos \phi_{ij} - y_{jk} \sin \phi_{ij} + x_{ij} \\ x_{jk} \sin \phi_{ij} + y_{jk} \cos \phi_{ij} + y_{ij} \\ \phi_{ij} + \phi_{jk} \end{bmatrix} \]
We call this operation compounding, and it is used to calculate the resultant relationship from two given relationships which are arranged head-to-tail. It would be used, for instance, to determine the location of a mobile robot after a sequence of relative motions. Remember that these transformations involve rotations, so compounding is not merely vector addition.

Utilizing (8), the first-order estimate of the mean of the compounding operation is:

\[ \hat{x}_{ik} \approx \hat{x}_{ij} \oplus \hat{x}_{jk}. \]

Also, from (9), the first-order estimate of the covariance is:

\[ C(\hat{x}_{ik}) \approx J_\oplus \begin{bmatrix} C(\hat{x}_{ij}) & C(\hat{x}_{ij}, \hat{x}_{jk}) \\ C(\hat{x}_{jk}, \hat{x}_{ij}) & C(\hat{x}_{jk}) \end{bmatrix} J_\oplus^T, \]

where the Jacobian of the compounding operation, \( J_\oplus \) is given by:

\[
J_\oplus = \frac{\partial (\hat{x}_{ij} \oplus \hat{x}_{jk})}{\partial (\hat{x}_{ij}, \hat{x}_{jk})} = \begin{bmatrix}
1 & 0 & -(y_k - y_j) & \cos \phi_{ij} & -\sin \phi_{ij} & 0 \\
0 & 1 & (x_k - x_j) & \sin \phi_{ij} & \cos \phi_{ij} & 0 \\
0 & 0 & 1 & 0 & 0 & 1
\end{bmatrix}.
\]

3.2.2 The Inverse Relationship

Given a relationship \( x_{ij} \), the formula for the coordinates of the inverse relationship \( x_{ji} \), as a function of \( x_{ij} \) is:

\[
x_{ji} \doteq \hat{x}_{ij} \oplus \hat{x}_{ij} = \begin{bmatrix}
-x_{ij} \cos \phi_{ij} - y_{ij} \sin \phi_{ij} \\
x_{ij} \sin \phi_{ij} - y_{ij} \cos \phi_{ij} \\
-x_{ij}
\end{bmatrix}.
\]

We call this the reverse relationship. Using (8) we get the first-order mean estimate:

\[ \hat{x}_{ji} \approx \hat{x}_{ij}. \]

and from (9) the first-order covariance estimate is:

\[ C(x_{ji}) \approx J_\oplus C(x_{ij}) J_\oplus^T. \]

where the Jacobian for the reversal operation, \( J_\oplus \) is:

\[
J_\oplus = \frac{\partial x_{ji}}{\partial x_{ij}} = \begin{bmatrix}
-\cos \phi_{ij} & -\sin \phi_{ij} & y_{ji} \\
\sin \phi_{ij} & \cos \phi_{ij} & -x_{ji} \\
0 & 0 & 1
\end{bmatrix}.
\]

Note that the uncertainty is not inverted, but rather expressed from the opposite (reverse) point of view.

3.2.3 Composite Relationships

We have shown how to compute the resultant of two relationships which are arranged head-to-tail, and also how to reverse a relationship. With these two operations we can calculate the resultant of any sequence of relationships.

For example, the resultant of a chain of relationships arranged head-to-tail can be computed recursively by:

\[ x_{it} = x_{ij} \oplus x_{ji} = x_{ij} \oplus (x_{jk} \oplus x_{kl}) \]

\[ = x_{ik} \oplus x_{kl} \rightarrow (x_{ij} \oplus x_{jk}) \oplus x_{kl} \]

Note, the compounding operation is associative, but not commutative.
We have denoted the reversal operation by $\otimes$ so that by analogy to conventional $+$ and $-$ we may write:

$$x_{ij} \otimes x_{kj} \Delta x_{ij} \otimes (\otimes x_{kj}).$$

This is the head-to-head combination of two relationships.

The tail-to-tail combination arises quite often (as in figure 1), and is given by:

$$x_{jk} = \otimes x_{ij} \otimes x_{ik}$$

To estimate the mean of a complex relationship, such as the tail-to-tail combination, we merely solve the estimate equations recursively:

$$\hat{x}_{jk} = \hat{x}_{ij} \otimes \hat{x}_{ik} = \otimes \hat{x}_{ij} \otimes \hat{x}_{ik}$$

The covariance can be estimated in a similar way:

$$C(x_{jk}) \approx \mathbf{J}_\otimes \begin{bmatrix} C(x_{ij}) & C(x_{ji}, x_{ik}) \\ C(x_{ik}, x_{ij}) & C(x_{ik}) \end{bmatrix} \mathbf{J}^T_\otimes$$

$$\approx \mathbf{J}_\otimes \begin{bmatrix} \mathbf{J}_\otimes C(x_{ij}) \mathbf{J}^T_\otimes & C(x_{ij}, x_{ik}) \mathbf{J}^T_\otimes \\ \mathbf{J}_\otimes C(x_{ik}, x_{ij}) & C(x_{ik}) \end{bmatrix} \mathbf{J}^T_\otimes.$$

This method is easy to implement as a recursive algorithm. An equivalent method is to precompute the Jacobians of useful combinations of relationships such as the tail-to-tail combination by using the chain rule. Thus, the Jacobian of the tail-to-tail relationship, $\otimes \mathbf{J}_\otimes$ is given by:

$$\otimes \mathbf{J}_\otimes \Delta \frac{\partial x_{jk}}{\partial (x_{ij}, x_{ik})} = \frac{\partial x_{jk}}{\partial (x_{ij}, x_{ik})} \frac{\partial (x_{ij}, x_{ik})}{\partial (x_{ij}, x_{ik})}$$

$$= \mathbf{J}_\otimes \begin{bmatrix} \mathbf{J}_\otimes 0 \\ 0 \mathbf{I} \end{bmatrix} = \begin{bmatrix} \mathbf{J}_1 \otimes \mathbf{J}_2 \otimes \mathbf{J}_2 \end{bmatrix}.$$  

Comparison will show that these two methods are symbolically equivalent, but the recursive method is easier to program, while pre-computing the composite Jacobians is more computationally efficient. Even greater computational efficiency can be achieved by making a change of variables such that the already computed mean estimate is used to evaluate the Jacobian, much as described earlier and in Appendix A.

It may appear that we are calculating first-order estimates of first-order estimates of ..., but actually this recursive procedure produces precisely the same result as calculating the first-order estimate of the composite relationship. This is in contrast to min-max methods which make conservative estimates at each step and thus produce very conservative estimates of a composite relationship.

If we now assume that the cross-covariance terms in the estimate of the covariance of the tail-to-tail relationship are zero, we get:

$$C(x_{jk}) \approx \mathbf{J}_1 \otimes \mathbf{J}_2 \otimes \mathbf{J}_2 \mathbf{J}^T_1 \mathbf{J}^T_2 \mathbf{J}_2 + \mathbf{J}_1 \otimes \mathbf{C}(x_{ik}) \mathbf{J}^T_1 \mathbf{J}_2$$

The Jacobians for six degree-of-freedom compounding and reversal relationships are given in Appendix A.

### 3.2.4 Extracting Relationships

We have now developed enough machinery to describe the procedure for estimating the relationships between objects which are in our map. The map contains, by definition, estimates of the locations of objects with respect to the world frame; these relations can be extracted directly. Other relationships are implicit, and must be extracted, using methods developed in the previous sections.

For any general spatial relationship among world locations we can write:

$$y = g(x).$$

The estimated mean and covariance of the relationship are given by:

$$\bar{y} \approx g(\bar{x}),$$

$$C(y) \approx \mathbf{G}_x \mathbf{C}(x) \mathbf{G}_x^T.$$  

In our mobile robot example we will need to be able to estimate the relative location of one object with respect to the coordinate frame of another object in our map. In this case, we would simply substitute the tail-to-tail operation previously discussed for the function $g$.

$$y = x_{ij} = \otimes x_i \otimes x_j.$$  

275
4 Building the Map

Our map represents uncertain spatial relationships among objects referenced to a common world frame. Entries in the map may change for two reasons:

- An object moves.
- New spatial information is obtained.

To change the map, we must change the two components that define it — the (mean) estimate of the system state vector, \( \mathbf{x} \), and the estimate of the system variance matrix, \( \mathbf{C}(\mathbf{x}) \). Figure 6 shows the changes in the system due to moving objects, or the addition of new spatial information (from sensing).

We will assume that new spatial information is obtained at discrete moments, marked by states \( k \). The update of the estimates at state \( k \), based on new information, is considered to be instantaneous. The estimates, at state \( k \), prior to the integration of the new information are denoted by \( \hat{\mathbf{x}}_{k}^{(-)} \) and \( \mathbf{C}(\hat{\mathbf{x}}_{k}^{(-)}) \), and after the integration by \( \hat{\mathbf{x}}_{k}^{(+)n} \) and \( \mathbf{C}(\hat{\mathbf{x}}_{k}^{(+n)}) \).

In the interval between states the system may be changing dynamically — for instance, the robot may be moving. When an object moves, we must define a process to extrapolate the estimate of the state vector and uncertainty at state \( k - 1 \), to state \( k \) to reflect the changing relationships.

4.1 Moving Objects

Before describing how the map changes as the mobile robot moves, we will present the general case, which treats any processes that changes the state of the system.

The system dynamics model, or process model, describes how components of the system state vector change (as a function of time in a continuous system, or by discrete transitions).

Between state \( k - 1 \) and \( k \), no measurements of external objects are made. The new state is determined only by the process model, \( f \), as a function of the old state, and any control variables applied in the process (such as relative motion commands sent to our mobile robot). The process model is thus:

\[
\mathbf{x}_{k}^{(-)} = f\left(\hat{\mathbf{x}}_{k-1}^{(+)n}, \mathbf{y}_{k-1}\right),
\]

where \( \mathbf{y} \) is a vector comprised of control variables, \( \mathbf{u} \), corrupted by mean-zero process noise, \( \mathbf{w} \), with covariance \( \mathbf{C}(\mathbf{w}) \). That is, \( \mathbf{y} \) is a noisy control input to the process, given by:

\[
\mathbf{y} = \mathbf{u} + \mathbf{w}.
\]

Given the estimates of the state vector and variance matrix at state \( k - 1 \), the estimates are extrapolated to state \( k \) by:

\[
\hat{\mathbf{x}}_{k}^{(-)} \approx f\left(\hat{\mathbf{x}}_{k-1}^{(+)n}, \mathbf{y}_{k-1}\right),
\]

\[
\mathbf{C}(\hat{\mathbf{x}}_{k}^{(-)}) \approx \mathbf{F}(\mathbf{x}, \mathbf{y}) \mathbf{C}(\mathbf{x}_{k-1}^{(+n)}),
\]

where,

\[
\mathbf{F}(\mathbf{x}, \mathbf{y}) = \left[ \begin{array}{cc}
\mathbf{F}_{x} & \mathbf{F}_{y}
\end{array} \right] \cong \frac{\partial f(\mathbf{x}, \mathbf{y})}{\partial(x, y)} \left( \hat{\mathbf{x}}_{k-1}^{(+)n}, \mathbf{y}_{k-1} \right)
\]
If the process noise is uncorrelated with the state, then the off-diagonal sub-matrices in the matrix above are 0 and the covariance estimate simplifies to:

$$C(x_k^{(-)}) \approx F_x C(x_{k-1}^{(+)}))F_x^T + F_y C(y_{k-1})F_y^T.$$ 

The new state estimates become the current estimates to be extrapolated to the next state, and so on.

In our example, only the robot moves, so the process model need only describe its motion. A continuous dynamics model can be developed given a particular robot, and the above equations can be reformulated as functions of time (see [Gelb, 1984]). However, if the robot only makes sensor observations at discrete times, then the discrete motion approximation is quite adequate.

When the robot moves, it changes its relationship, $x_R$, with the world. The robot makes an uncertain relative motion, $y_R = u_R + w_R$, to reach a final world location $x_k$. Thus,

$$x_R = x_R \oplus y_R.$$ 

Only a small portion of the map needs to be changed due to the change in the robot's location from state to state — specifically, the $R$th element of the estimated mean of the state vector, and the $R$th row and column of the estimated variance matrix. Thus, $x_{k-1}^{(+)}$ becomes $x_{k}^{(-)}$:

$$\hat{x}_{k-1}^{(+)} = \begin{bmatrix} \hat{x}_{R} \\
\end{bmatrix}, \quad \hat{x}_{k}^{(-)} = \begin{bmatrix} \hat{x}_{R} \\
\end{bmatrix},$$

and, analogously, $C(x_{k-1}^{(+)}))$ becomes:

$$C(x_k^{(-)}) = \begin{bmatrix} B' & A' \\
\end{bmatrix}$$

where:

$$\hat{x}'_R \approx \hat{x}_R \oplus \hat{y}_R,$$

$$A' = C(x'_R) \approx J_1 c(x_R) J_1^T + J_2 c(y_R) J_2^T:$$

$$B'_R = C(x'_R, x_1) \approx J_1 c(x_R, x_1).$$

$A'$ is the covariance matrix representing the uncertainty in the new location of the robot. $B'$ is a row in the system variance matrix. The $i$th element is a sub-matrix — the cross-covariance of the robot's estimated location and the estimated location of the $i$th object, as given above. If the estimates of the two locations were not dependent, then that sub-matrix was, and remains 0. The newly estimated cross-covariance matrices are transposed, and written into the $R$th column of the system variance matrix, marked by $B'^T$.

4.2 New Spatial Information

The second process which changes the map is the update that occurs when new information about the system state is incorporated. New spatial information might be given, determined by sensor measurements, or even deduced as the consequence of applying a geometrical constraint. For example, placing a box on a table reduces the degrees of freedom of the box and eliminates the uncertainties in the lost degrees of freedom (with respect to the table coordinate frame). In our example, state information is obtained as prior knowledge, or through measurement.

There are two cases which arise when adding new spatial information about objects to our map:

- I: A new object is added to the map,
- II: A (stochastic) constraint is added between objects already in the map.

We will consider each of these cases in turn.
4.2.1 Case I: Adding New Objects

When a new object is added to the map, a new entry must be made in the system state vector to describe the object's world location. A new row and column are also added to the system variance matrix to describe the uncertainty in the object's estimated location, and the inter-dependencies of this estimate with estimated locations of other objects. The expanded system is:

\[
\begin{bmatrix}
\hat{x}^{(+)} \\
\hat{\mathbf{C}}^{(+)} \\
\hat{x}_{n+1}
\end{bmatrix} =
\begin{bmatrix}
\hat{x}^{(-)} \\
\mathbf{B} \\
\mathbf{A}
\end{bmatrix}
\]

where \( \hat{x}_{n+1}, \mathbf{A}, \) and \( \mathbf{B} \) will be defined below.

We divide Case I into two sub-cases: I-a, the estimate of the new object's location is independent of the estimates of other object locations described in the map; or I-b, it is dependent on them.

Case I-a occurs when the estimated location of the object is given directly in world coordinates — i.e., \( \hat{x}_{\text{new}} \) and \( \mathbf{C}(\hat{x}_{\text{new}}) \) — perhaps as prior information. Since the estimate is independent of other location estimates:

\[
x_{n+1} = x_{\text{new}},
\]

\[
\hat{x}_{n+1} = \hat{x}_{\text{new}},
\]

\[
\mathbf{A} = \mathbf{C}(x_{n+1}) = \mathbf{C}(x_{\text{new}}),
\]

\[
\mathbf{B} = \mathbf{C}(x_{n+1} | x_i) = \mathbf{C}(x_{\text{new}} | x_i) = 0.
\]

Case I-b occurs when the world location of the new object is determined as a function, \( g \), of its spatial relation, \( z \), to other object locations estimated in the map. The relation might be measured or given as prior information. For example, the robot measures the location of a new object relative to itself. Clearly, the uncertainty in the object's world location is correlated with the uncertainty in the robot's (world) location. For Case I-b:

\[
x_{n+1} = g(x, z),
\]

\[
\hat{x}_{n+1} = g(\hat{x}, z),
\]

\[
\mathbf{A} = \mathbf{C}(x_{n+1}) = \mathbf{G}_x \mathbf{C}(x) \mathbf{G}_x^T + \mathbf{G}_y \mathbf{C}(z) \mathbf{G}_y,
\]

\[
\mathbf{B} = \mathbf{G}_x \mathbf{C}(x).
\]

We see that Case I-a is the special case of Case I-b, where estimates of the world locations of new objects are independent of the old state estimates and are given exactly by the measured information. That is, when:

\[
g(x, z) = z.
\]

4.2.2 Case II: Adding Constraints

When new information is obtained relating objects already in the map, the system state vector and variance matrix do not increase in size; i.e., no new elements are introduced. However, the old elements are constrained by the new relation, and their values will be changed.

Constraints can arise in a number of ways:
A robot measures the relationship of a known landmark to itself (i.e., estimates of the world locations of robot and landmark already exist).

A geometric relationship, such as colinearity, coplanarity, etc., is given for some set of the object location variables.

In the first example the constraint is noisy (because of an imperfect measurement). In the second example, the constraint could be absolute, but could also be given with a tolerance.

There is no mathematical distinction between the two cases; we will describe all constraints as if they came from measurements by sensors — real sensors or pseudo-sensors (for geometric constraints), perfect measurement devices or imperfect. A pseudo-sensor which measures "rectangular-ness" is discussed later in the example.

When a constraint is introduced, there are two estimates of the geometric relationship in question — our current best estimate of the relation, which can be extracted from the map, and the new sensor information. The two estimates can be compared (in the same reference frame), and together should allow some improved estimate to be formed (as by averaging, for instance).

For each sensor, we have a sensor model that describes how the sensor maps the spatial variables in the state vector into sensor variables. Generally, the measurement, \( z \), is described as a function, \( h \), of the state vector, corrupted by mean-zero, additive noise \( v \). The covariance of the noise, \( C(v) \), is given as part of the model.

\[
z = h(x) + v. \tag{15} 
\]

The conditional sensor value, given the state, and the conditional covariance are easily estimated from (15) as:

\[
\hat{z} \approx h(\hat{x}). 
\]

\[
C(z) \approx H_x C(x) H_x^T + C(v), 
\]

where:

\[
H_x \triangleq \frac{\partial h_k(x)}{\partial x} (x^{(-)}) 
\]

The formulae describe what values we expect from the sensor under the circumstances, and the likely variation; it is our current best estimate of the relationship to be measured. The actual sensor values returned are usually assumed to be conditionally independent of the state, meaning that the noise is assumed to be independent in each measurement, even when measuring the same relation with the same sensor. The actual sensor values, corrupted by the noise, are the second estimate of the relationship.

For simplicity, in our example we assume that the sensor measures the relative location of the observed object in Cartesian coordinates. Thus the sensor function becomes the tail-to-tail relation of the location of the sensor and the sensed object, described in Section 3.2.3. (Formally, the sensor function is a function of all the variables in the state vector, but the unused variables are not shown below):

\[
z = x_{ij} = \Theta x_i \oplus x_j.
\]

\[
\hat{z} = \hat{x}_{ij} = \Theta \hat{x}_i \oplus \hat{x}_j.
\]

\[
C(z) = \Theta J_\Theta \left[ \begin{array}{cc} C(x_i) & C(x_i, x_j) \\ C(x_j, x_i) & C(x_j) \end{array} \right] \Theta J_\Theta^T + C(v).
\]

Given the sensor model, the conditional estimates of the sensor values and their uncertainties, and an actual sensor measurement, we can update the state estimate using the Kalman Filter equations [Gelb, 1984] given below, and described in the next section:

\[
\hat{x}^{(+)}_k = \hat{x}^{(-)}_k + K_k [z_k - h_k(\hat{x}^{(-)}_k)], 
\]

\[
C(\hat{x}^{(+)}_k) = C(\hat{x}^{(-)}_k) - K_k H_x C(x^{(-)}_k), \tag{16} 
\]

\[
K_k = C(\hat{x}^{(-)}_k) H_x^T [H_x C(x^{(-)}_k) H_x^T + C(v)_k]^{-1}. 
\]
4.2.3. Kalman Filter

The updated estimate is a weighted average of the two estimates, where the weighting factor (computed in the weight matrix \( K \)) is proportional to the prior covariance in the state estimate, and inversely proportional to the conditional covariance of the measurement. Thus, if the measurement covariance is large, compared to the state covariance, then \( K \rightarrow 0 \), and the measurement has little impact in revising the state estimate. Conversely, when the prior state covariance is large compared to the noise covariance, then \( K \rightarrow I \), and nearly the entire difference between the measurement and its expected value is used in updating the state.

The Kalman Filter generally contains a system dynamics model defined less generally than presented in (10); in the standard filter equations the process noise is additive:

\[
x_k^{(-)} = f\left(x_{k-1}^{(+)}, u_{k-1}\right) + w_{k-1}
\]

in that case \( F_X \) of (10) is the identity matrix, and the estimated mean and covariance take the form:

\[
x_k^{(-)} \approx f\left(x_{k-1}^{(+)}, u_{k-1}\right),
\]

\[
C(x_k^{(-)}) \approx F_X C(x_{k-1}^{(+)}) F_X^T + C(w_{k-1}).
\]

If the functions \( f \) in (17) and \( h \) in (15) are linear in the state vector variables, then the partial derivative matrices \( F \) and \( H \) are simply constants, and the update formulae (16) with (17), (15), and (18), represent the Kalman Filter [Gelb, 1984].

If, in addition, the noise variables are drawn from normal distributions, then the Kalman Filter produces the \textit{optimal minimum-variance Bayesian estimate}, which is equal to the mean of the \textit{a posteriori conditional density function} of \( x \), given the prior statistics of \( x \), and the statistics of the measurement \( z \). No non-linear estimator can produce estimates with smaller mean-square errors.

If the noise does not have a normal distribution, then the Kalman Filter is not optimal, but produces the optimal \textit{linear} estimate.

If the functions \( f \) and \( h \) are \textit{non-linear} in the state variables, then \( F \) and \( H \) will have to be evaluated (they are not constant matrices). The given formulae then represent the Extended Kalman Filter, a sub-optimal non-linear estimator. It is one of the \textit{most widely used non-linear estimators} because of its simplicity to the optimal linear filter, its simplicity of implementation, and its ability to provide accurate estimates in practice.

The error in the estimation due to the non-linearities in \( h \) can be greatly reduced by iteration, using the Iterated Extended Kalman Filter equations [Gelb, 1984]:

\[
\hat{x}_{k, i+1}^{(+)} = \hat{x}_k^{(-)}
\]

\[
+ K_{k,i} \left[ z_k - \left( h_k(\hat{x}_{k,i}^{(+)} + H_X(\hat{x}_k^{(-)} - \hat{x}_{k,i}^{(+)})) \right) \right],
\]

\[
C(\hat{x}_{k,i+1}^{(+)} = C(\hat{x}_k^{(-)}) - K_{k,i} H_X C(x_k^{(-)}),
\]

\[
K_{k,i} = C(x_k^{(-)}) H_X \left[ H_X C(x_k^{(-)}) H_X^T + C(v_k) \right]^{-1},
\]

where:

\[
H_X \triangleq \frac{\partial h_k(x)}{\partial x} (\hat{x}_k^{(-)})
\]

\[
\hat{x}_{k,0}^{(+)} \triangleq \hat{x}_k^{(-)}.
\]

Note that the original measurement value, \( z \), and the prior estimates of the mean and covariance of the state, are used in each step of the iteration. The ith estimate of the state is used to evaluate the weight matrix, \( K \), and is the argument to the non-linear sensor function, \( h \). Iteration can be carried out until there is little further improvement in the estimate. The final estimate of the covariance need only be computed at the end of iteration, rather than at each step, since the intermediate system covariance estimates are not used.
5 Developed Example

The methods developed in this paper will now be applied to the mobile robot example in detail. We choose the world reference frame to be the initial location of the robot, without loss of generality. The robot's initial location with respect to the world frame is then the identity relationship (of the compounding operation), with no uncertainty.

\[ \hat{x} = [\hat{x}_R] = 0, \]

\[ C(x) = [C(x_R)] = 0, \]

Note, that the normal distribution corresponding to this covariance matrix (from (4)) is singular, but the limiting case as the covariance goes to zero is a dirac delta function centered on the mean estimate. This agrees with the intuitive interpretation of zero covariance implying no uncertainty.

Step 1: When the robot senses object #1, the new information must be added into the map. Normally, adding new information relative to the robot's position would fall under case 1-b, but since the robot's frame is the same as the world frame, it falls under case 1-a. The sensor returns the mean location and variance of object #1 (\(z_1\) and \(C(z_1)\)). The new system state vector and variance matrix are:

\[ \hat{x} = \begin{bmatrix} \hat{x}_R \\ \hat{x}_1 \end{bmatrix} = \begin{bmatrix} 0 \\ \hat{z}_1 \end{bmatrix}, \]

\[ C(x) = \begin{bmatrix} C(x_R) & C(x_R, x_1) \\ C(x_1, x_R) & C(x_1) \end{bmatrix} = \begin{bmatrix} C(y_R) & 0 \\ 0 & C(z_1) \end{bmatrix}. \]

We can now transform the information in our map from the world frame to the robot's new frame to see how the world looks from the robot's point of view:

\[ \hat{x}_{RW} = \Theta \hat{x}_R, \]

\[ C(x_{RW}) \approx J_\Theta C(x_R) J_\Theta^T. \]

Step 3: The robot now senses an object from its new location. The new measurement, \(z_2\), is of course, relative to the robot's location, \(x_R\).

\[ \hat{x} = \begin{bmatrix} \hat{x}_R \\ \hat{x}_1 \\ \hat{x}_2 \end{bmatrix} = \begin{bmatrix} \hat{z}_1 \\ \hat{z}_2 \end{bmatrix}, \]

\[ C(x) = \begin{bmatrix} C(x_R) & C(x_R, x_1) & C(x_R, x_2) \\ C(x_1, x_R) & C(x_1) & C(x_1, x_2) \\ C(x_2, x_R) & C(x_2, x_1) & C(x_2) \end{bmatrix} = \begin{bmatrix} C(y_R) & 0 & C(y_R) J_1 \Theta \\ 0 & C(z_1) & 0 \\ J_1 \Theta C(y_R) J_1 \Theta & 0 & C(x_2) \end{bmatrix}. \]

where:

\[ C(x_2) = J_1 \Theta C(y_R) J_1 \Theta + J_2 \Theta C(z_2) J_2 \Theta. \]

Step 4: Now, the robot senses object #1 again. In practice one would probably calculate the world
FOUR UNCERTAIN POINTS

APPLYING THE RECTANGLE CONSTRAINT

Figure 7:

location of a new object, and only after comparing
the new object to the old ones could the robot de­
cide that they are likely to be the same object. For
this example, however, we will assume that the sen­
or is able to identify the object as being object #1
and we don't need to map this new measurement
into the world frame before performing the update.

The symbolic expressions for the estimates of the
mean and covariance of the state vector become
too complex to reproduce as we have done for the
previous steps. Also, if the iterated methods are
being used, there is no symbolic expression for the
results.

Notice that the formulae presented in this section
are correct for any network of relationships which
has the same topology as this example. This pro­
cedure can be completely automated, and is very
suitable for use in off-line robot planning.

As a further example of some of the possibilities
of this stochastic map method, we will present an
example of a geometric constraint — four points
known to be arranged in a rectangle. Figure 7
shows the estimated locations of the four points
with respect to the world frame, before and after
introduction of the information that they are the
vertices of a rectangle. The improved estimates are
overlayed on the original estimates in the "after"
diagram. We model the rectangle constraint as we
would any other sensor (with mean-zero noise):

\[
\mathbf{z} = h(\mathbf{x}) + \mathbf{v}.
\]

In this case, we need a pseudo-sensor which
measures the "rectangularity" of four points —
\(x_i, x_j, x_k, x_l\) labeled counter-clockwise from the
lower-right corner:

\[
\mathbf{z} = \begin{bmatrix}
  x_i - x_j + x_k - x_l \\
  y_i - y_j + y_k - y_l \\
  (x_i - x_j)(x_k - x_l) + (y_i - y_j)(y_k - y_l)
\end{bmatrix}.
\]

The first two elements of \(\mathbf{z}\) are zero when oppo­
site sides of the closed planar figure represented by
the four vertices are parallel; the last element of
\(\mathbf{z}\) is zero when the two sides forming the upper­
right corner are perpendicular. Given four esti­
mated points, the prior conditional value of \(\mathbf{z}\) and
the estimated covariance can be computed. The
new information — the "measurement" returned
by the pseudo-sensor will be drawn from a dis­
tribution with mean 0 and covariance determined
by how much tolerance in the "rectangularity" pa­
rameters is acceptable. In fact, if we are going to
impose the constraint that the four points are pre­
cisely in a rectangle — i.e., there is no measurement
noise, \(\mathbf{C}(\mathbf{v}) = 0\) — then we can choose \(h\) to be any
function which is zero only when the four points
are in a rectangle. If, however, we wish to impose
a loose rectangle constraint, we must formulate the
function \(h\) such that \(\mathbf{z}\) is a useful measure of how
the four points fail to be rectangular.
6 Discussion and Conclusions

This paper presents a general theory for estimating uncertain relative spatial relationships between reference frames in a network of uncertain spatial relationships. Such networks arise, for example, in industrial robotics and navigation for mobile robots, because the system is given spatial information in the form of sensed relationships, prior constraints, relative motions, and so on. The theory presented in this paper allows the efficient estimation of these uncertain spatial relations. This theory can be used, for example, to compute in advance whether a proposed sequence of actions (each with known uncertainty) is likely to fail due to too much accumulated uncertainty; whether a proposed sensor observation will reduce the uncertainty to a tolerable level; whether a sensor result is so unlikely given its expected value and its prior probability of failure that it should be ignored, and so on. This paper extends the theory of state estimation to include information in the form of uncertain spatial relations between many different frames.

The estimation procedure makes a number of assumptions that are normally met in practice. These assumptions are detailed in the text, but the main assumptions can be summarized as follows:

- The angular errors are "small". This requirement arises because we linearize inherently nonlinear relationships. In Monte Carlo simulations [Smith, 1985], angular errors with a standard deviation as large as 5° gave estimates of the means and variances to within 1% of the correct values.

- Estimating only two moments of the probability density functions of the uncertain spatial relationships is adequate for decision making. We believe that this is the case since we will most often model a sensor observation by a mean and variance, and the relationships which result from combining many pieces of information become rapidly Gaussian, and thus are accurately modelled by only two moments.

The theory presented in this paper can be extended to adaptively improve the models it uses. For example, if the noise term in a camera model is too large, the observed errors will be smaller on average than expected. Adaptive filtering methods can be incorporated into the methods described to improve model estimates.

Although the examples presented in this paper have been solely concerned with spatial information, there is nothing in the theory that imposes this restriction. Provided that functions are given which describe the relationships among the components to be estimated, those components could be forces, velocities, time intervals, or other quantities in robotic and non-robotic applications.
Appendix A

Earlier in this paper we presented formulae for computing the resultant of two spatial relationships in two dimensions (three degrees of freedom). In three dimensions, there are six degrees of freedom: translations in \( x, y, z \) and three orientation variables: \( \phi, \theta, \psi \). There are two common interpretations of these orientation variables—Euler angles and roll, pitch, and yaw, defined below.

Euler Angles

Euler angles are defined by:

\[
Euler(\phi, \theta, \psi) = Rot(x, \phi)Rot(y', \theta)Rot(z'', \psi)
\]

The head to tail relationship is then given by:

\[
x_3 = \begin{bmatrix}
  x_3 \\
  y_3 \\
  z_3 \\
  \phi_3 \\
  \theta_3 \\
  \psi_3
\end{bmatrix} = \begin{bmatrix}
  T_E \\
  A_E
\end{bmatrix}
\]

where \( T_E \) and \( A \) are defined by:

\[
T_E = R_1 \begin{bmatrix}
  x_2 \\
  y_2 \\
  z_2
\end{bmatrix} + \begin{bmatrix}
  x_1 \\
  y_1 \\
  z_1
\end{bmatrix}, \quad A = \begin{bmatrix}
  \text{atan2}(a_{y_3}, a_{z_3}) \\
  \text{atan2}(a_{x_3} \cos \phi_3 + a_{y_3} \sin \phi_3, a_{z_3}) \\
  \text{atan2}(-n_{x_3} \sin \phi_3 + n_{y_3} \cos \phi_3, -o_{x_3} \sin \phi_3 + o_{y_3} \cos \phi_3)
\end{bmatrix}
\]

where \( R_1 \) is defined below and \( a_{x_3} \) etc. are the corresponding elements of the compound rotation matrix \( R_3 \), defined by \( R_3 = R_1 R_2 \). Note that the inverse trigonometric function \( \text{atan2} \) is a function of two arguments, the ordinate \( y \) and the abscissa \( x \). This function returns the correct result when either \( x \) or \( y \) are zero, and gives the correct answer over the entire range of possible inputs [Paul, 1981].

The Jacobian of this relationship, \( J \), is:

\[
J = \frac{\partial x_3}{\partial(x_1, x_2)} = \begin{bmatrix}
  I_{3 \times 3} & M & R_{Euler} & 0_{3 \times 2} \\
  0_{3 \times 3} & K_1 & 0_{3 \times 3} & K_2
\end{bmatrix}
\]

\[
M = \begin{bmatrix}
- (y_3 - y_1) & (x_3 - x_1) \cos(\phi_1) & o_{x_1} y_2 - n_{x_1} y_2 \\
(x_3 - x_1) & (x_3 - x_1) \sin(\phi_1) & o_{y_1} y_2 - n_{y_1} y_2 \\
0 & -x_2 \cos \phi_1 \cos \psi_1 + y_2 \cos \phi_1 \sin \psi_1 - z_2 \sin \phi_1 & o_{z_1} y_2 - n_{z_1} y_2
\end{bmatrix}
\]

\[
R_1 = \begin{bmatrix}
  n_{x_1} & o_{x_1} & a_{x_1} \\
  n_{y_1} & o_{y_1} & a_{y_1} \\
  n_{z_1} & o_{z_1} & a_{z_1}
\end{bmatrix}
\]

28
The inverse relation, $x'$, in terms of the elements of the relationship $x$, using the Euler angle definition, is:

$$x' = \begin{bmatrix} x' \\ y' \\ z' \\ \phi' \\ \theta' \\ \psi' \end{bmatrix} = \begin{bmatrix} -y_2 x_n + y_n z \\ -y_2 y_n + x_2 z_n \\ -y_2 z_n + x_2 y_n + x_3 z_n \\ -y_2 x_n + y_n z \\ -y_2 y_n + x_2 z_n \\ -y_2 z_n + x_2 y_n + x_3 z_n \end{bmatrix}$$

where $n_x$ etc. are the elements of the rotation matrix $R$ defined above.

The Jacobian of the inverse Euler relationship is:

$$J = \frac{\partial x'}{\partial x} = \begin{bmatrix} -R^T \ N \\ 0_{3\times3} \ Q \end{bmatrix}, \quad Q = \begin{bmatrix} 0 & 0 & -1 \\ 0 & -1 & 0 \\ -1 & 0 & 0 \end{bmatrix}.$$

**Roll, Pitch, and Yaw Angles**

Roll, pitch, and yaw angles are defined by:

$$R_{PY}(\phi, \theta, \psi) = \text{Rot}(x, \phi)\text{Rot}(y', \theta)\text{Rot}(z'', \psi)$$

The Jacobian of the head-to-tail relationship, with roll, pitch, and yaw variables is given by:

$$J = \frac{\partial x_3}{\partial (x_1, x_2)} = \begin{bmatrix} 1_{9\times3} \ M \ R_{R_{PY}} \ 0_{3\times3} \\ 0_{3\times3} \ K_1 \ 0_{3\times3} \ K_2 \end{bmatrix}.$$
\[
M = \begin{bmatrix}
-(y_3 - y_1) & (x_3 - z_1) \cos(\phi_1) & a_{x_1} y_2 - a_{z_1} z_2 \\
-x_3 - x_1 & (x_3 - z_1) \sin(\phi_1) & a_{x_1} y_2 - a_{y_1} x_2 \\
0 & -x_2 \cos(\theta_1) - y_2 \sin(\theta_1) \sin(\psi_1) - x_2 \sin(\theta_1) \cos(\psi_1) & a_{x_1} y_2 - a_{z_1} z_2 \\
\end{bmatrix}
\]

\[
R_1 = \begin{bmatrix}
\eta_{x_1} & a_{x_1} & a_{x_1} \\
\eta_{y_1} & a_{y_1} & a_{y_1} \\
\eta_{z_1} & a_{z_1} & a_{z_1}
\end{bmatrix}
\]

\[
K_1 = \begin{bmatrix}
1 & [\sin(\theta_3 \sin(\phi_3 - \phi_1))]/\cos(\theta_3) & [\cos(\phi_3 + a_{z_3} \cos(\psi_3))/\cos(\theta_3) \\
0 & \cos(\phi_3) \sin(\phi_3 - \phi_1)] & \cos(\phi_3) \sin(\phi_3 - \phi_1)]/\cos(\theta_3) \\
0 & [\sin(\theta_3 \sin(\phi_3 - \phi_1))]/\cos(\theta_3) & [\cos(\phi_3 + a_{z_3} \cos(\psi_3))/\cos(\theta_3) \\
\end{bmatrix}
\]

\[
K_2 = \begin{bmatrix}
[\cos(\theta_2 \cos(\psi_3 - \psi_2))]/\cos(\theta_3) & [\cos(\theta_2 \cos(\psi_3 - \psi_2))]/\cos(\theta_3) & 0 \\
[\cos(\theta_2 \sin(\psi_3 - \psi_2))]/\cos(\theta_3) & [\cos(\theta_2 \sin(\psi_3 - \psi_2))]/\cos(\theta_3) & 0 \\
[a_{x_3} \cos(\phi_3 + a_{y_3} \sin(\phi_3))/\cos(\theta_3) & [\sin(\theta_3 \sin(\psi_3 - \psi_2))]/\cos(\theta_3) & 0 \\
\end{bmatrix}
\]

Note that for both definitions, the Jacobian has been simplified by the use of final terms (e.g. \(x_3, \psi_3\)). Since the final terms are computed routinely in determining the mean relationship, they are available to evaluate the Jacobian. Examination of the elements indicates the possibility of a singularity; as the mean values of the angles approach a singular combination, the accuracy of the covariance estimates using this Jacobian will decrease. Methods for avoiding the singularity during calculations are being explored.
