HIGHLIGHTS
• A model to quantitatively predict the fracture toughness based on the orbital overlap at the Fermi is introduced.
• The toughness of $\text{Pd}_{57.4}\text{Al}_{23.5}\text{Y}_{7.8}\text{Ni}_{11.3}$ metallic glass is predicted to be $95 \pm 20 \text{ MPa} \cdot \text{m}^{0.5}$.
• $\text{Pd}_{57.4}\text{Al}_{23.5}\text{Y}_{7.8}\text{Ni}_{11.3}$ metallic glasses show pronounced plasticity and absence of crack growth in micro-mechanical cantilever bending experiments consistent with the predicted toughness.

GRAPHICAL ABSTRACT

ABSTRACT

High fracture toughness is crucial for the application of metallic glasses as structural materials to avoid catastrophic failure of the material in a brittle manner. One fingerprint for fracture toughness in metallic glasses is the fraction of hybridized bonds, which is affected by alloying $\text{Pd}_{57.4}\text{Al}_{23.5}\text{Y}_{7.8}\text{M}_{11.3}$ with $\text{M} = \text{Fe}, \text{Ni}, \text{Cu}, \text{Os}, \text{Ir}, \text{Pt}, \text{and Au}$. It is shown that experimental fracture toughness data is correlated to the fraction of hybridized bonds which scale with the localized bonds at the Fermi level. Thus, the localized bonds at the Fermi level are utilized quantitatively as a measure for fracture toughness. Based on $\text{ab initio}$ calculations, the minimum fraction of hybridized bonds was identified for $\text{Pd}_{57.4}\text{Al}_{23.5}\text{Y}_{7.8}\text{Ni}_{11.3}$. According to the ansatz that the crystal orbital overlap population at the Fermi level scales with fracture toughness, for $\text{Pd}_{57.4}\text{Al}_{23.5}\text{Y}_{7.8}\text{Ni}_{11.3}$ a value of around $95 \pm 20 \text{ MPa} \cdot \text{m}^{0.5}$ is predicted quantitatively for the first time. Consistent with this prediction, in micro-mechanical beam bending experiments $\text{Pd}_{57.4}\text{Al}_{23.5}\text{Y}_{7.8}\text{Ni}_{11.3}$ thin films show pronounced plasticity and absence of crack growth.

1. Introduction

Some metallic glasses envisaged for mechanical applications have a high strength [1–3] and show the capability of plastic deformation, especially in geometries confined to the size of the plastic zone [4,5], which can be in the range of millimeters [6]. Plasticity in metallic glasses is especially reported to occur under bending load [7–10]. Lewandowski et al. put the Poisson's ratio $\nu$ forward as a design criterion for brittleness and toughness by reporting a brittle to ductile transition at $\nu = 0.31–0.32$ [11]. However, as this brittle to ductile transition is not universal [9,12,13], Schnabel et al. proposed the fraction of hybridized...
bonds compared to the overall bonding as an electronically motivated measure for high fracture toughness [12] as covalent bonding induces brittleness in metallic glasses [10,14]. Decreasing the fraction of hybridized bonds [12] is therefore proposed to serve as a guideline for increasing fracture toughness. Based on this approach the surface of hybridized bonds presented here enables the quantitative prediction of fracture toughness of metallic glasses for the first time. In this model, the crystal orbital overlap population [15] at the Fermi level is utilized as a measure to quantify localized bonds. By correlating the localized bonds with fracture toughness values reported in literature, the fracture toughness of 49.0 MPa·m^{0.5} reported by Schnabel et al. [12], the Pd_{57.0}Al_{23.9}Y_{7.8}Cu_{11.4} metallic glass is chosen as a reference and Pd_{57.0}Al_{23.9}Y_{7.8}M_{11.4} (M = Fe, Ni, Os, Ir, Pt, and Au) as the model system with the aim to understand the relationship between electronic structure and fracture toughness by quantification of the fraction of hybridized bonds.

2. Methods

2.1. Ab initio calculations

The electronic structure of metallic glasses is the basis for the quantitative model introduced here to predict fracture toughness. To investigate the electronic structure of Pd_{57.0}Al_{23.9}Y_{7.8}M_{11.4} metallic glasses, ab initio molecular dynamics calculations were carried out in this study to determine the fraction of hybridized bonds. Therefore, the density functional theory [16] based openMX code [17,18] was used by employing electronic potentials with the generalized gradient approximation [19]. The following linear combinations of localized pseudoatomic orbitals [20] were applied as basis functions: Pd_{5.0-s}p_{1d1}, Al_{6.0-s}p_{2d2}, Y_{6.5-s}p_{2d2}, Cu_{5.0-s}p_{2d2}, Os_{5.0-s}p_{2d2}, Ir_{5.0-s}p_{2d2}, Pt_{5.0-s}p_{2d2}. Thereby, the first symbol designates the chemical element followed by the cutoff-radius of the potential in Bohr radii. The last set of symbols defines the primitive orbitals. A grid of 85x85x85 N-points and a cutoff energy of 150 Ry have been used. The Vienna Ab-initio Simulation Package (VASP) [21,22] was employed for volume relaxation at 0 K. Therefore, ultrafast pseudopotentials were employed and the Brillouin zone was integrated at a 3 x 3 x 3 Monkhorst-Pack k-point grid [23]. For the calculation of the electronic structure, projector augmented-wave potentials [22,24] were utilized. The Crystal Orbital Overlap Populations (COOP) [15] and Crystal Hamilton Overlap Populations (COHP) [25] were calculated by the projection of the wavefunction onto localized orbitals using the LOBSTER code (version 2.2.1) [26–28], taking all atomic orbitals in the supercell into account. For visualization, all atomic interactions within the first coordination shell of every atom are considered. To generate glasses structures comparable to experimental samples, the procedure introduced by Hrostert et al. [29] was applied. Thereby, a supercell of 115 atoms was heated for 400 fs to 4000 K by scaling the velocities and then quenched to 0 K. Afterwards the volume of the structure was relaxed. The heating-quenching-relaxation cycle was repeated until the volume difference between two subsequent cycles was lower than 2%. To obtain the bulk modulus, the volume-energy data were fitted with the Birch-Murnaghan equation of state [30]. From the atomic positions, the reduced pair distribution function (PDF) g(r) was calculated [29].

2.2. Sample synthesis and characterization

Metallic glass thin films were synthesized by magnetron sputtering from elemental targets on silicon and NaCl-substrates in DC mode in an ultra-high vacuum combinatorial growth system [31] with a base pressure lower than 8 x 10^{-5} Pa. The substrate potential was kept floating and no intentional heating was applied. The target to substrate distance was 10 cm. For silicon substrates, no sample rotation was applied to achieve Pd—Ni and Al—Y gradients, from which the position with the calculated composition was selected. For NaCl-substrates, the sample was rotated with 30 rounds per minute to obtain a homogeneous film. The power densities at the targets were 4.2, 4.8, 1.7 and 1.3 W/cm² for Pd, Al, Y, and Ni, respectively. Ar was the working gas with a pressure of 0.4 Pa during sputtering [12]. After deposition, the NaCl substrates were dissolved in water, to obtain thin film flakes which were cleaned in isopropanol and acetone prior to the X-ray measurements. Thin films deposited onto silicon substrates were used for micromechanical testing.

High energy X-ray diffraction (HEXRD) was carried out on beamline P02.1 [32] of the PETRA III electron storage ring at DESY, Hamburg, Germany, X-rays with a wavelength of 0.20701 Å were utilized. Data were collected with a Perkin Elmer XRD1621 fast detector and processed by applying the FIT2D software [33–35]. The data were corrected for background scattering and the structure factor as well as pair distribution functions calculated by a fast Fourier transformation implemented in the PDFgetX3 software package [36]. The composition of the sample was investigated with an EDAX Genesis 2000 detector on a JEOL JSM-6480 scanning electron microscope. The electronic structure was explored by X-ray photoelectron spectroscopy in a JEOL JAMP 9500F Field Emission Auger microscope.

The fracture toughness was evaluated using pre-notched micro specimens [37–39] produced via focused ion beam (FIB) milling in a Zeiss Auriga® Dual Beam FIB from 1 μm thick metallic glass thin films deposited onto Si substrates. Single cantilever bending on pre-notched specimen was used to reduce the possible impact of residual stresses [40]. The ion beam current was sequentially reduced from 2 nA to 50 pA for notching. The nominal dimensions of the cantilever were 1 x 1 x 0.1 μm with a crack length of 200 μm and a final bending length of 10 μm to meet the geometric requirements [41,42] on the used geometry factors. Subsequently, four samples were tested in a Zeiss Gemini 500 field emission scanning electron microscope equipped with an Asmec Unat II in situ indenter. The indenter operates in an intrinsic displacement controlled mode [43]. Numerous unloading segments were introduced to the applied displacement function to evaluate crack propagation via the unloading stiffness following the small scale approach of Wurster et al. [44]. While small scale fracture tests are not in full geometric accordance with the ASTM K_{IC} measurement standard, reproducible values for fracture toughness are obtained and reported here as K_{IC} [43].

Atom probe tomography (APT) specimens were prepared from the center of the metallic glass thin film deposited on a silicon substrate using an FEI Helios 600 following procedures described in Ref. [45]. APT measurements were carried out on a Cameca LEAP 3000® HR operated in voltage mode at a pulse repetition rate of 200 kHz, a pulse rate of 15% and the base temperature was set to 60 K. Data analysis was performed using the IVAS 3.8.2 software package.

3. Results and discussion

Pd_{57.0}Al_{23.9}Y_{7.8}Cu_{11.3} was reported by Schnabel et al. [12] to exhibit a fracture toughness of 49 MPa·m^{0.5}. Thus, Pd_{57.0}Al_{23.9}Y_{7.8}Cu_{11.3} was selected as a reference system in the present study. To investigate the composition dependence of the fraction of localized bonds on the overall bonding, Cu in Pd_{57.0}Al_{23.9}Y_{7.8}Cu_{11.3} has been substituted by Fe, Ni, Co, Os, Ir, Pt, and Au, i.e. by screening group 8-11 elements in the 4th and 6th period of the periodic table of elements. In the following, the
results of the ab initio calculations are presented. Based on the calculated electronic structure and fracture toughness data from literature, a quantitative model to predict the fracture toughness is introduced. Thereafter, the theoretical atomic scale topology is contrasted to experimental data. Finally, the predicted fracture toughness data and results of micro-mechanical bending tests are compared to critically appraise the prediction.

The total and partial electronic densities of states (DOS) of Pd$_{57.4}$Al$_{23.5}$Y$_{7.8}$M$_{11.3}$ (M = Cu, Ir, Au, Ni) are presented in Fig. 1 for the energy range of $-10$ to $0$ eV below the Fermi level. The total DOS consist of the sum of the partial DOS of every atom in the supercell of the calculation. The partial DOS contains the summed DOS of all atoms of a certain species. For the partial DOS, the DOS for the s, p and d bands are shown separately to differentiate the individual orbital contributions. The DOS are smoothed by adjacent averaging with a smooth window of 7 data points to enhance clarity. Fig. 1a shows the DOS for the reference material Pd$_{57.4}$Al$_{23.5}$Y$_{7.8}$Cu$_{11.3}$ [12]. By comparing peak positions and shapes for the main constituents Pd and Al between $-5$ and $-2$ eV weak p-d hybridization as well as weak s-d hybridization around $-6$ eV is observed. While the Y d-band shows only minor overlap with the Pd d-band, strong d-d hybridization between Cu and Pd is present over the complete energy range of $-6$ to $0$ eV populated in the Cu DOS.

Following the approach of Schnabel et al. [12], the hybridizing constituent Cu in the reference Pd$_{57.4}$Al$_{23.5}$Y$_{7.8}$Cu$_{11.3}$ was substituted in the simulations by Ir, Fe, Os, Pt, Au, Ni to identify a less hybridizing constituent. All compositions discussed here have in common that the main alloy constituents Pd and Al show weak pd- and sd-hybridization between $-6$ and $-2$ eV and that the Y d-band overlaps only slightly with other bands (Fig. 1b-d), as has already been discussed for the reference material above. Therefore, the focus will be on the differences induced by the Cu-substituting element.

The partial DOS of Pd$_{57.4}$Al$_{23.5}$Y$_{7.8}$Ir$_{11.3}$ (Fig. 1b) resemble those of Pd$_{57.4}$Al$_{23.5}$Y$_{7.8}$Cu$_{11.3}$. The Ir d-states are more evenly distributed between $-6$ eV and the Fermi level compared to Cu (Fig. 1a). But as for Pd$_{57.4}$Al$_{23.5}$Y$_{7.8}$Cu$_{11.3}$, hybridization is evident from the partial DOS of the Ir and Pd d-bands. This type of electronic structure of Pd$_{57.4}$Al$_{23.5}$Y$_{7.8}$Ir$_{11.3}$ and Pd$_{57.4}$Al$_{23.5}$Y$_{7.8}$Cu$_{11.3}$ is representative for Pd$_{57.4}$Al$_{23.5}$Y$_{7.8}$M$_{11.3}$ alloyed with M = Fe, Os, and Pt (Fig. S1 in the supplementary information).

In contrast to Pd$_{57.4}$Al$_{23.5}$Y$_{7.8}$Cu$_{11.3}$, the energy range populated by the Au d-band between $-6$ and $-2$ eV in Pd$_{57.4}$Al$_{23.5}$Y$_{7.8}$Au$_{11.3}$ (Fig. 1c) is rather narrow and only weak hybridization with the Pd d-band is found between $-6$ and $-4$ eV. In this energy range, however, the total DOS is dominated by the Au d-band. Around $-4$ eV, sd-hybridization is observed between Al and Au. Due to the small overlap of the Au d-band with the populated states of the other constituents and its domination of the total DOS between $-6$ and $-4$ eV, Au should be a suitable candidate element for the substitution of Cu in Pd$_{57.4}$Al$_{23.5}$Y$_{7.8}$Cu$_{11.3}$ to obtain a metallic glass with high fracture toughness through a low fraction of hybridized bonds.

In the DOS of Pd$_{57.4}$Al$_{23.5}$Y$_{7.8}$Ni$_{11.3}$ (Fig. 1d), the Ni d-band populates a small energy range between $-4$ eV and $0$ eV similar to
Pd\textsubscript{57.4}Al\textsubscript{23.5}Y\textsubscript{7.8}Au\textsubscript{11.3}. In this energy range, the Pd d-band becomes less populated, which leads to less hybridization while the Ni d-band dominates the total DOS. In contrast to Pd\textsubscript{57.4}Al\textsubscript{23.5}Y\textsubscript{7.8}Au\textsubscript{11.3}, due to the vicinity to the Fermi level, the hybridizing states of Ni form weaker bonds compared to the hybridizing states of Au in Pd\textsubscript{57.4}Al\textsubscript{23.5}Y\textsubscript{7.8}Au\textsubscript{11.3} that are located at lower energies [15].

Based on the qualitative DOS analysis above, Ni is identified as the most promising candidate to substitute Cu in Pd\textsubscript{57.4}Al\textsubscript{23.5}Y\textsubscript{7.8}Cu\textsubscript{11.3} with respect to fracture toughness. While Ir hybridizes strongly with Pd, Au populates only a narrow energy range around \(-6\) eV. However, Ni shows qualitatively the lowest fraction of hybridized bonds on the overall bonding of the transition metals studied here and the hybridizing states of Ni form weak bonds due to the vicinity to the Fermi level [15], thereby promoting shear relaxation.

The bonding and anti-bonding contributions in the Pd-based metallic glass were investigated by the COHP depicted in Fig. 2a. The COHP of Pd\textsubscript{57.4}Al\textsubscript{23.5}Y\textsubscript{7.8}Ir\textsubscript{11.3} is smoothed by a Savitzky-Golay [46] filter to enhance the clarity of the graphical representation. According to Rempp [47], these oscillations for Pd\textsubscript{57.4}Al\textsubscript{23.5}Y\textsubscript{7.8}Ir\textsubscript{11.3} could be caused by the energy difference between the Ir d- and both s- and p-bands.

Fig. 2a shows that the COHPs of the Pd-based metallic glasses from Fig. 1 resemble each other. Below approximately \(-2.4\) eV, the COHPs are negative, indicating bonding contributions to the overall bonding. Above \(-2.4\) eV, all Pd-based metallic glasses show anti-bonding contributions to the bonding. Comparing the COHPs of Pd\textsubscript{57.4}Al\textsubscript{23.5}Y\textsubscript{7.8}Ir\textsubscript{11.3} to the reference system Pd\textsubscript{57.4}Al\textsubscript{23.5}Y\textsubscript{7.8}Cu\textsubscript{11.3}, a slight shift of the COHP above \(-2.8\) eV towards the Fermi level is identified, while it resembles the reference COHP of Pd\textsubscript{57.4}Al\textsubscript{23.5}Y\textsubscript{7.8}Cu\textsubscript{11.3} below \(-2.8\) eV. The resulting higher population of anti-bonding states at the Fermi-level indicates weaker bonding. Pd\textsubscript{57.4}Al\textsubscript{23.5}Y\textsubscript{7.8}Au\textsubscript{11.3} exhibits fewer bonding contributions than the reference Pd\textsubscript{57.4}Al\textsubscript{23.5}Y\textsubscript{7.8}Cu\textsubscript{11.3} between \(-5\) and \(-3.3\) eV, which is part of the energy range dominated by the Au d-band, while its anti-bonding states resemble the reference material. Thus, the lower population of bonding states and the lower fraction of hybridized bonds observed in Fig. 1 results in weaker localized bonds between \(-5\) and \(-3.3\) eV, which may, in turn, enable shear relaxation upon mechanical loading. In contrast to this, the COHP of
Pd$_{57.4}$Al$_{23.5}$Y$_{7.8}$Ni$_{11.3}$ resembles the COHP of the reference material in the bonding region, while the anti-bonding contributions are smaller than the reference and shifted to the Fermi-level similar to Pd$_{57.4}$Al$_{23.5}$Y$_{7.8}$Ir$_{11.3}$. Taking into account the integrated COHP (ICOHP) as a measure of bond strength [48], Pd$_{57.4}$Al$_{23.5}$Y$_{7.8}$Ni$_{11.3}$ exhibits weaker bonding than Pd$_{57.4}$Al$_{23.5}$Y$_{7.8}$Au$_{11.3}$, as its ICOHP of $-0.509$ eV is less negative and hence indicates weaker bond strength than $-0.589$ eV for Pd$_{57.4}$Al$_{23.5}$Y$_{7.8}$Au$_{11.3}$, which is consistent with the qualitative DOS analysis above.

Comparing the COHP of Pd$_{57.4}$Al$_{23.5}$Y$_{7.8}$Cu$_{11.3}$ and Pd$_{57.4}$Al$_{23.5}$Y$_{7.8}$Ni$_{11.3}$ with the COHP of brittle Cu$_{69.6}$Zr$_{30.4}$ [12], the similarly tough but nearly twice as strong Co$_{53.0}$Ta$_{7.0}$B$_{40.0}$ [49] and tough Pt$_{57.4}$Cu$_{14.8}$Ni$_{5.2}$P$_{22.6}$ [4] shows that Pd$_{57.4}$Al$_{23.5}$Y$_{7.8}$Ni$_{11.3}$ is similar to the Pt-based metallic glass. Contrary to Pd$_{57.4}$Al$_{23.5}$Y$_{7.8}$Ni$_{11.3}$, Pt$_{57.4}$Cu$_{14.8}$Ni$_{5.2}$P$_{22.6}$ exhibits more bonding states between $-8$ and $-5$ eV and at the same time more anti-bonding states close to the Fermi level. Due to the presence of stronger bonding states below $-5$ eV, Pt$_{57.4}$Cu$_{14.8}$Ni$_{5.2}$P$_{22.6}$ is expected to be more shear resistant than Pd$_{57.4}$Al$_{23.5}$Y$_{7.8}$Ni$_{11.3}$. Nevertheless, as the COHP of Pt$_{57.4}$Cu$_{14.8}$Ni$_{5.2}$P$_{22.6}$ and Pd$_{57.4}$Al$_{23.5}$Y$_{7.8}$Ni$_{11.3}$ are similar, also the fracture toughness is expected to be similar. The brittle Cu$_{69.6}$Zr$_{30.4}$, in contrast, exhibits anti-bonding states only between $-2$ and $-3$ eV and hence bonding states close to the Fermi level, indicating strong, hybridized bonds. The COHP of Co$_{53.0}$Ta$_{7.0}$B$_{40.0}$ contains a broad energy range populated by bonding states, anti-bonding states are only present above $-1$ eV close to the Fermi level. Due to the larger amount of bonding contributions and thus stronger hybridized bonding, the shear resistance in the latter two glasses is predicted to be larger compared to Pt$_{57.4}$Cu$_{14.8}$Ni$_{5.2}$P$_{22.6}$ and the Pd-based glasses. This prediction is consistent with the brittle behavior reported for Cu$_{69.6}$Zr$_{30.4}$ [12].

![Fracture toughness as a function of COOP at the Fermi level.](image)

**Fig. 3.** (a) Fracture toughness as a function of COOP at the Fermi level. Values for fracture toughness were obtained from literature [4,50–54] and COOP calculated by ab initio methods. The solid red line represents a linear fit. The blue dashed line marks the COOP at $E_F$ of Pd$_{57.4}$Al$_{23.5}$Y$_{7.8}$Ni$_{11.3}$. Dotted blue lines mark the minimum and maximum predicted fracture toughness values of Pd$_{57.4}$Al$_{23.5}$Y$_{7.8}$Ni$_{11.3}$. Note that the fracture toughness of all glasses included in the fit was obtained under similar loading conditions. (b) COOP of metallic glasses from (a) including glasses from Fig. 1. Negative values indicate anti-bonding contributions, positive values bonding contributions. The inset is a magnification of the marked region close to the Fermi level. (For interpretation of the references to color in this figure legend, the reader is referred to the web version of this article.)
Pd$_{57.4}$Al$_{23.5}$Y$_{7.8}$Ni$_{11.3}$ clearly exhibits the smallest population of anti-
constituent of the alloys. The difference between the Pd-based metallic
that the difference between the COOPs depends mainly on the major
–
teresting
data may be affected by sample size: The fracture toughness of
mote bond separation [55] and hence favor brittle behavior of metallic
glasses. Antibonding states increase the total bond energy and thus pro-
at the Fermi level must be considered for the design of tough metallic
ating and anti-bonding states between
Fig. 3b). While all material systems exhibit a transition between bond-
larger amount of free volume promotes fracture toughness by lowering
energy barrier for shear transformation and plastic deformation [56], the
plastic deformation behavior of the experimental sample is expected
to be more enhanced than predicted with the fracture toughness pre-
dicted serving as a lower bound. Fig. 4b compares the theoretical DOS
with the experimental DOS. Due to the high energy of the X-rays in the
XPS (1.49 keV) as well as the temperature in the experiment
(298 K in experiment vs. 0 K in the calculation), the experimental DOS
experiences severe peak broadening. Thereby, one broad hump is ob-
served for the valence band, that covers the energy range of the more
detailed theoretical DOS. The comparison between calculated and mea-
sured topology and electronic structure confirms the significance of the
ab initio modeled structure.

The fracture toughness of non-magnetic metallic glasses reported in
literature [450–54] is presented in Fig. 3a) as a function of the COOP at
the Fermi level. Therefore, we use the same data set for fracture tough-
ness as Demetriou et al. [50] expanded by the data from Schnabel et al.
[12]. These data are fitted by a linear fit excluding fracture toughness
values of Pd$_{79.3}$Ag$_{13.3}$Pd$_{62.1}$Cu$_{14.8}$Ni$_{5.2}$P$_{22.6}$ and Pd$_{77.4}$Al$_{23.3}$Y$_{7.8}$Cu$_{11.3}$, as these data may be affected by sample size: The fracture toughness of
Pd$_{79.3}$Ag$_{13.3}$Pd$_{62.1}$Cu$_{14.8}$Ni$_{5.2}$P$_{22.6}$ might be overestimated because the plastic
zone size of 6 mm is larger than the actual sample size [50] of 2.1
× 2.1 × 20 mm$^3$ in two dimensions [5]. Fracture toughness of
Pd$_{77.4}$Al$_{23.3}$Y$_{7.8}$Cu$_{11.3}$ is determined by the J-integral and might be sam-
ple size dependent [12]. The COOP at the Fermi level of
Pd$_{77.4}$Al$_{23.3}$Y$_{7.8}$Ni$_{11.3}$ is predicted to be around 95 ± 20 MPa·m$^{0.5}$. Comparing this prediction with the Ashby map reported by Demetriou et al.
[50], this predicted fracture toughness corresponds to a plastic zone size
in the orders of 0.1 to 1 mm [50]. Furthermore, this analysis shows that in addition to the presence of localized bonds, also anti-bonding states
at the Fermi level must be considered for the design of tough metallic
glasses. Antibonding states increase the total bond energy and thus pro-
mote bond separation [55] and hence favor brittle behavior of metallic
glasses. Due to the promotion of bond separation, not only the fracture
toughness is affected by anti-bonding states, but also the cohesive en-
ergy and hence the elastic properties (cf. Fig. S2). The free volume in
ab initio calculations is small and different free volume configurations
were not tested. Hence, the free volume content is smaller than it
might be in physical samples, as shown in Fig. 4 below. However, as a
larger amount of free volume promotes fracture toughness by lowering
the energy barrier for shear transformation and plastic deformation
[56], the fracture toughness predicted based on the electronic structure
serves as a lower bound while free volume affects the variability of frac-
ture toughness observed in Fig. 3a.

The COOP of the glasses presented in Figs. 1 and 3a) are shown in
Fig. 3b). While all material systems exhibit a transition between bond-
ing and anti-bonding states between −5 and −3 eV, the amount of anti-
bonding states close to the Fermi level differs significantly. It is evident
that the difference between the COOPs depends mainly on the major
constituent of the alloys. The difference between the Pd-based metallic
glasses is hence rather small (inset Fig. 3b). Nevertheless, Pd$_{57.4}$Al$_{23.3}$Y$_{7.8}$Ni$_{11.3}$ clearly exhibits the smallest population of anti-
bonding states at the Fermi level (COOP($E_f$)$_{Ni}$ = −0.01278), whereas
Pd$_{57.4}$Al$_{23.3}$Y$_{7.8}$Cu$_{11.3}$ – from a qualitative point of view (Fig. 1) also
interestig – displays a larger population of antibonding states at the
Fermi level (COOP($E_f$)$_{Au}$ = −0.01910). Therefore, the predicted
fracture toughness of approximately 95 ± 20 MPa·m$^{0.5}$ of
Pd$_{57.4}$Al$_{23.3}$Y$_{7.8}$Ni$_{11.3}$ is the largest within the here considered group of metallic glasses.

Since the Ni-containing Pd-based metallic glass is the most promis-
ing candidate in terms of fracture toughness, this composition was syn-
thesized by magnetron sputtering in the form of a Pd$_{57.4}$Al$_{25.8}$Y$_{7.9}$Ni$_{12.2}$
thin film on silicon and Pd$_{52.2}$Al$_{27.4}$Y$_{4.2}$Ni$_{18.2}$ for the thin film flakes. The
constituents are homogeneously distributed based on the frequency
distribution analysis performed on data collected by atom probe-
tomography (see Fig. S3 in supplementary information). Hence, chemi-
inhomogeneities on the here probed length scale cannot be revealed
by atom probe tomography. To critically appraise the predicted topol-
ogy, the calculated pair distribution function is compared to the exper-
imentally obtained one in Fig. 4a. Considering the slight differences
between the composition of the powder and the calculation, the pair
distribution functions are in reasonable agreement. However, the first
peak of the experimental pair distribution function is shifted to a larger
bond distance compared to the theoretical one. This indicates that the
synthesized material is less frustrated, most likely due to the presence
of free volume. As the energy barrier for shear transformation and thus
plastic deformation, which is required for high fracture toughness,
decreases with increasing free volume content in the sample [56], the
plastic deformation behavior of the experimental sample is expected
to be more enhanced than predicted with the fracture toughness pre-
dicted serving as a lower bound. Fig. 4b compares the theoretical DOS
with the experimental DOS. Due to the high energy of the X-rays in the
XPS (1.49 keV) as well as the temperature in the experiment
(298 K in experiment vs. 0 K in the calculation), the experimental DOS
experiences severe peak broadening. Thereby, one broad hump is ob-
served for the valence band, that covers the energy range of the more
detailed theoretical DOS. The comparison between calculated and mea-
sured topology and electronic structure confirms the significance of the
ab initio modeled structure.

Fig. 4. (a) Calculated and experimental pair distribution function of Pd$_{57.4}$Al$_{23.3}$Y$_{7.8}$Ni$_{11.3}$
and Pd$_{52.2}$Al$_{27.4}$Y$_{4.2}$Ni$_{18.2}$, respectively. The experimental PDF has already been published
in [57]. (b) Calculated density of states of Pd$_{57.4}$Al$_{23.3}$Y$_{7.8}$Ni$_{11.3}$ and the valence band of
Pd$_{52.2}$Al$_{27.4}$Y$_{4.2}$Ni$_{18.2}$, measured by XPS.
To investigate the fracture toughness of the Pd57.4Al23.5Y7.8Ni11.3 metallic glass, beams were prepared for micro-mechanical testing (Fig. 5a). The unloading slopes (S in Fig. 5d) performed after 2, 2.5, 3, and 3.5 μm displacement do not change indicating an absence of crack extension. Also, at the final displacement of 4 μm, the beam did not fracture (Fig. 5b). In contrast, multiple shear-bands are formed not only around the pre-notch but also on the compressive side of the cantilever (Fig. 5c) indicating significant plastic deformation. The shear bands do not cross the neutral axis which indicates that shear band propagation is suppressed by the stress gradient and the change from tensile to compressive stresses across cantilever. Therefore, catastrophic shear band propagation is prevented because the suppressed shear band propagation requires the activation of new shear bands (see Fig. 5c) and allows the glass to deform plastically without catastrophic crack development [5] up to the final displacement of 4 μm Since no evidence for crack extension was obtained in post mortem imaging, the fracture toughness exceeds the constraints of micromechanical fracture experiments. This is in agreement with the high fracture toughness expected from the plot in Fig. 3, which would require substantially larger samples to quantitatively proof the enormous fracture toughness [5,58]. Such sample dimensions are – in light of the chemical composition and technological constraints – currently not feasible.

4. Conclusions

Inspired by the qualitative notion of Schnabel et al. [12] that the fraction of bonds stemming from hybridized states compared to the overall bonding can be associated with damage tolerance in thin film metallic glasses, a correlation between the fraction of localized and anti-bonding bonds scaling with the crystal orbital overlap population at the Fermi level and experimental fracture toughness data was identified. It is shown that a low number of anti-bonding states at the Fermi-level is a necessary requirement for high fracture toughness. The electronic structures of Pd57.4Al23.5Y7.8Ni11.3 (M = Fe, Ni, Cu, Os, Ir, Pt, and Au) have been calculated by ab initio methods. Pd57.4Al23.5Y7.8Ni11.3 was identified to exhibit the minimal fraction of hybridized bonds of the materials investigated. Moreover, the correlation between the fraction of localized anti-bonding bonds scaling with the crystal orbital overlap population at the Fermi level and experimental fracture toughness data was identified. This correlation allows the quantitative prediction of fracture toughness of metallic glasses that is crucial for the design of tough metallic glasses. With this model, the fracture toughness of Pd57.4Al23.5Y7.8Ni11.3 is predicted to be 95 ± 20 MPa·m0.5, being the first fracture toughness value predicted quantitatively for a metallic glass based on the electronic structure. Consistent with this prediction, micro-mechanical beam bending experiments show that Pd57.4Al23.5Y7.8Ni11.3 thin films exhibit superior fracture toughness and form multiple shear bands.
