Abstract

Answer-set programming (ASP) has emerged recently as a viable programming paradigm. We describe here an ASP system, DATALOG with constraints or DC, based on non-monotonic logic. Informally, DC theories consist of propositional clauses (constraints) and of Horn rules. The semantics is a simple and natural extension of the semantics of the propositional logic. However, thanks to the presence of Horn rules in the system, modeling of transitive closure becomes straightforward. We describe the syntax, use and implementation of DC and provide experimental results.

General Info

DC is an answer set programming (ASP) system similar to propositional logic but extended to include Horn clauses. The semantics of DC is a natural extension of the semantics of propositional logic. The DC system is implemented in two modules, ground and dcs, which are written in the ‘C’ programming language and compiled with ggc. There are approximately 2500 lines of code for ground and approximately 1500 for dcs. DC has been implemented on both SUN SPARC and a PC running linux.

A DC theory (or program) consists of constraints and Horn rules (DATALOG program). This fact motivates our choice of terminology — DATALOG with constraints. We start a discussion of DC with the propositional case. Our language is determined by a set of atoms $A_T$. $A_T$ is a set of propositional clauses $\neg a_1 \lor \ldots \lor \neg a_m \lor b_1 \lor \ldots \lor b_n$ such that all $a_i$ and $b_j$ are from $A_T$.

A DC theory (or program) is a triple $T_{dc} = (T_C,T_H,T_{PC})$, where

1. $T_C$ is a set of propositional clauses $\neg a_1 \lor \ldots \lor \neg a_m \lor b_1 \lor \ldots \lor b_n$ such that all $a_i$ and $b_j$ are from $A_T$.
2. $T_H$ is a set of Horn rules $a_1 \land \ldots \land a_m \Rightarrow b$ such that $b \in A_T$ and all $a_i$ are from $A_T$.
3. $T_{PC}$ is a set of clauses over $A_T$.

By $A_T(T_{dc})$, $A_T(T_{dc})$ and $A_TPC(T_{dc})$ we denote the set of atoms from $A_T$, $A_T$ and $A_TPC$, respectively, that actually appear in $T_{dc}$.

With a DC theory $T_{dc} = (T_C,T_H,T_{PC})$ we associate a family of subsets of $A_T(T_{dc})$. We say that a set $M \subseteq A_T(T_{dc})$ satisfies $T_{dc}$ (is an answer set of $T_{dc}$) if

1. $M$ satisfies all the clauses in $T_C$, and
2. the closure of $M$ under the Horn rules in $T_H$, $M^c = LM(T_H \cup M)$ satisfies all clauses in $T_{PC}$ ($LM(P)$ denotes the least model of a Horn program $P$).

Intuitively, the collection of clauses in $T_C$ can be thought of as a representation of the constraints of the problem, Horn rules in $T_H$ can be viewed as a mechanism to compute closures of sets of atoms satisfying the constraints in $T_C$, and the clauses in $T_{PC}$ can be regarded as constraints on closed sets (we refer to them as post-constraints). A set of atoms $M \subseteq A_T(T_{dc})$ is a model if it (propositionally) satisfies the constraints in $T_C$ and if its closure (propositionally) satisfies the post-constraints in $T_{PC}$. Thus, the semantics of DC retains much of the simplicity of the semantics of propositional logic. DC was introduced by the authors in [ET00].

Applicability of the System

DC can be used as a computational tool to solve search problems. We define a search problem $\Pi$ to be determined by a set of finite instances, $D_I$, such that for each instance $I \in D_I$, there is a finite set $S_I(I)$ of all solutions to $\Pi$ for the instance $I$. For example, the problem of finding a hamilton cycle in a graph is a search problem: graphs are instances and for each graph, its hamilton cycles (sets of their edges) are solutions.

A DC theory $T_{dc} = (T_C,T_H,T_{PC})$ solves a search problem $\Pi$ if solutions to $\Pi$ can be computed (in polynomial time) from answer sets to $T_{dc}$. Propositional logic and stable logic programming [MT99, Nie98] are used as problem solving formalisms following the same general paradigm.

We will illustrate the use of DC to solve search problems by discussing the problem of finding a hamilton cycle in a directed graph. Consider a directed graph $G$ with the vertex set $V$ and the edge set $E$. Consider a set of atoms $\{hc(a,b); (a,b) \in E\}$. An intuitive interpretation of an atom $hc(a,b)$ is that the edge $(a,b)$ is in a hamilton cycle. Include in $T_C$ all clauses of the form $\neg hc(a,b) \lor \neg hc(c,a)$, where $a,b,c \in V$, $b \neq c$ and $(b,a), (c,a) \in E$. In addition, include in $T_C$ all clauses of the form $\neg hc(a,b) \lor \neg hc(a,c)$, where $a,b,c \in V$.
b \neq c \text{ and } (a, b), (a, c) \in E. \text{ Clearly, the set of propositional variables of the form } \{hc(a, b) : (a, b) \in F\}, \text{ where } F \subseteq E, \text{ satisfies all clauses in } T_L \text{ if and only if no two different edges in } F \text{ end in the same vertex and no two different edges in } F \text{ start in the same vertex. In other words, } F \text{ spans a collection of paths and cycles in } G. 

To guarantee that the edges in } F \text{ define a hamilton cycle, we must enforce that all vertices of } G \text{ are reached by means of the edges in } F \text{ if we start in some (arbitrarily chosen) vertex of } G. \text{ This can be accomplished by means of a simple Horn program. Let us choose a vertex, say } s, \text{ in } G. \text{ Include in } T_H \text{ the Horn rules } hc(s, t) \rightarrow vstd(t), \text{ for every edge } (s, t) \text{ in } G. \text{ In addition, include in } T_H \text{ Horn rules } vstd(t), hc(t, u) \rightarrow vstd(u), \text{ for every edge } (t, u) \text{ of } G \text{ not starting in } s. \text{ Clearly, the least model of } F \cup T_H, \text{ where } F \text{ is a sub-set of } E, \text{ contains precisely these variables of the form } vstd(t) \text{ for which } t \text{ is reachable from } s \text{ by a nonempty path spanned by the edges in } F. \text{ Thus, } F \text{ is the set of edges of a hamilton cycle of } G \text{ if and only if the least model of } F \cup T_H, \text{ contains variable } vstd(t) \text{ for every vertex } t \text{ of } G. \text{ Let us define } T_{PC} = \{vstd(t) : t \in V\} \text{ and } T_{ham}(G) = (T_C, T_H, T_{PC}). \text{ It follows that hamilton cycles of } G \text{ can be reconstructed (in linear time) from answer sets to the DC theory } T_{ham}(G). \text{ In other words, to find a hamilton cycle in } G, \text{ it is enough to find an answer set for } T_{ham}(G). \text{ This example illustrates the simplicity of the semantics of DC — it is only a slight adaptation of the semantics of propositional logic to the case when in addition to propositional clauses we also have Horn rules in the theories. It also illustrates the power of DC to generate concise encodings. All known propositional encodings of the hamilton-cycle problem require that additional variables are introduced to “count” how far from the starting vertex an edge is located. Consequently, propositional encodings are much larger and lead to inefficient solutions to the problem.}

**Description of the System**

In this section we will discuss general features of DC. First, we will discuss the language for encoding problems and give an example by showing the encoding of the hamiltonicity problem. Second, we will describe how we execute the DC system. Third, we will give some details concerning the implementation of dcs, our solver. Last we discuss the expressivity of DC.

In the previous section we described the logic of DC in the propositional case. Our definitions can be extended to the predicate case (without function symbols). Each constraint is treated as an abbreviation of a set of its ground substitutions. This set is determined by the set of constants appearing in the theory and by additional conditions associated with the constraint (we illustrate this idea later in this section). When constructing predicate DC-based solutions to a problem II we separate the representation of an instance to II from the constraints that define II. The representation of an instance of II is a collection of facts or the extensional database (EDB). The constraints and rules that define II will be referred to as the intensional database (IDB) and the language for writing the problem descriptions that constitute the IDB will be referred to as L_{dc}. The separation of IDB and EDB means only one predicate description of II is needed.

The modules of DC, ground and dcs provide a complete system for describing and finding solutions to problems. An IDB in L_{dc} along with a specific EDB are the input to ground. A grounded propositional theory T_{dc} is output by ground and used as input to dcs.

A problem description in L_{dc} defines predicates, declares variables, and provides a description of the problem using rules. The predicates are defined using types from the EDB. Similarly, the variables are declared using types from the EDB. The rules consist of constraints, Horn rules and post-constraints. The constraints and post-constraints use several constructs to allow a more natural modeling. These constructs could be directly translated to clauses. (We use them as shorthands to ensure the conciseness of encodings.)

We present here a brief discussion of the constraints, Horn rules and post-constraint in L_{dc} and their meanings. Let PRED be the set of predicates occurring in the IDB. For each variable X declared in the IDB the range R(X) of X is determined by the EDB.

\textbf{Select} \(n, m, \vec{Y}; p_1(\vec{X}), \ldots, p_i(\vec{X}, \vec{Y}))q(\vec{X}, \vec{Y}), \text{ where } n, m \text{ are nonnegative integers such that } n \leq m, q \in \text{ PRED} \text{ and } p_1, \ldots, p_i \text{ are EDB predicates or logical conditions (logical conditions can be comparisons of arithmetic expressions or string comparisons). The interpretation of this constraint is as follows: for every } \vec{x} \in R(\vec{X}) \text{ at least } n \text{ atoms and at most } m \text{ atoms in the set } \{q(\vec{x}, \vec{y}) : \vec{y} \in R(\vec{Y})\} \text{ are true.}

\textbf{Select} \(n, m, \vec{Y})q(\vec{X}, \vec{Y}), \text{ where } n, m \text{ are nonnegative integers such that } n \leq m, q \in \text{ PRED}. \text{ The interpretation of this constraint is as follows: for every } \vec{x} \in R(\vec{X}) \text{ at least } n \text{ atoms and at most } m \text{ atoms in the set } \{q(\vec{x}, \vec{y}) : \vec{y} \in R(\vec{Y})\} \text{ are true.}

\textbf{Select} \(n, m)q_1(\vec{X}), \ldots, q_j(\vec{X}), \text{ where } n, m \text{ are nonnegative integers such that } n \leq m, q_1, \ldots, q_j \in \text{ PRED}. \text{ The interpretation of this constraint is as follows: for every } \vec{x} \in R(\vec{X}) \text{ at least } n \text{ atoms and at most } m \text{ atoms in the set } \{q_1(\vec{x}), \ldots, q_j(\vec{x})\} \text{ are true.}

Certain choices of } n, m \text{ in any of the Select constraints allow construction of even more specific constraints in } T_{dc}:

\begin{itemize}
  \item \(n = m \text{ exactly } n \text{ atoms must be true.}\)
  \item \(n = 0 \text{ at most } m \text{ atoms must be true.}\)
  \item \(m = 999 \text{ at least } n \text{ atoms must be true.}\)
\end{itemize}

\textbf{NOT} \(q_1(\vec{X}), \ldots, q_i(\vec{X}), \text{ where } q_1, \ldots, q_i \in \text{ PRED}. \text{ For every } \vec{x} \in R(\vec{X}) \text{ at least one atom in the set } \{q_1(\vec{x}), \ldots, q_i(\vec{x})\} \text{ must be false.} \)

\(q_1(\vec{X})| \ldots | q_i(\vec{X}), \text{ where } q_1, \ldots, q_i \in \text{ PRED}. \text{ For every } \vec{x} \in R(\vec{X}) \text{ at least one atom in the set } \)

\]

Methodology

Here we show the encoding of a problem in DC. We will use the example of hamiltonicity of a graph which we discussed previously. Figure 2 shows the EDB format used by ground. This format is compatible to that used by smodels and others. However, we require that the EDB be in separate files from the IDB. The format for the EDB allows data to be entered as sets, ranges, or individual elements and constant values can be entered on the command line.

The IDB provides a definition of the problem in Ldc. The IDB file has three parts. First a definition of the variables, next the declaration of variables and last a set of constraints and Horn clauses. The types used in the IDB must be in the data file(s). For example, the only data types in the graph file (Fig. 1) are vtx and edge. Thus the only data types which can be used in the IDB are vtx and edge.

In the idbpred section of Fig. 2 we define two predicates, the vstd predicate and the hc predicate. The vstd predicate has one parameter of type vtx and hc has two parameters both of type vtx.

The idbvar section of Fig. 2 declares two variables X, Y both of type vtx.

The section containing the constraints, Horn clauses, and post-constraints is proceeded by the keyword idbrules (see Fig. 2). The order in which the rules are entered is not important. The first constraint, Select(1,1,Y;edge(X,Y))hc(X,Y), ensures that each vertex has exactly one outgoing edge. The second constraint, Select(1,1,X;edge(X,Y))hc(X,Y), requires that each vertex has exactly one incoming edge.

| Select(1,1,Y;edge(X,Y))hc(X,Y).  |
| Select(1,1,X;edge(X,Y))hc(X,Y).  |
| % Horn rules                     |
| Horn Forall(X,Y;X!=i,edge(X,Y))  |
| vstd(vtx), hc(X,Y) → vstd(Y).    |
| Horn Forall(X,Y;X==i,edge(X,Y))  |
| hc(X,Y) → vstd(Y).              |
| % post-constraints               |
| vstd(X).                        |

Figure 2: File showing IDB for the hamiltonicity of a graph. The types are from Fig. 1

The first Horn rule ranges over all X, Y such that edge(X,Y) ∈ EDB and X ≠ i where i is a constant used to initialize vstd(i). This rule requires both vstd(X) and hc(X,Y) to be true before we can assign the value true to vstd(Y). The second Horn rule only requires hc(X,Y) to be true before vstd(Y) is assigned value true; however, in this rule X is restricted to the value of i.

The last line is a post-constraint that requires vstd(X) to be true for all X ∈ R(X) ensuring that the cycle is closed.

Running the system

Here we will describe the steps for execution of the DC system. The first module of DC, ground, has as input a data file(s), a rule file and command line arguments. Output is the theory file which will be used as input to dcs. The theory is written to a file whose name is the catenation of the constants and file names given as command line arguments. The extension .tdc is then appended to the output file name. The command line arguments for ground:

\[ \text{ground -r rf -d df [-c label=v] [-V]} \]

Required arguments

- r rf is the file describing the problem. There must be exactly one rule file.
- d df must be one or more files containing data that will be used to instantiate the theory. It is often convenient to use more than one file for data.

Optional arguments

- c This option allows use of constants in both data and rule files. When label is found while reading either
file it is replaced by \textit{v}. \textit{v} can be any string that is valid for the data type. If \textit{label} is to be used in a range then \textit{v} must be an integer. For example, if the data file contains the entry \texttt{queens[1..q]}, then we can define the constant \textit{q} with the option \texttt{-c q=8}. If more than one constant is needed then \texttt{-c b=3 n=14} defines both constants \textit{b},\textit{n} using the \texttt{-c} option.

\texttt{-V} The verbose options sends output to stdout during the execution of \texttt{ground}. This output may be useful for debugging of the data or rule files.

For the example of hamiltonicity we could have a data file (see Fig. \[\] named \texttt{1.gph} and an IDB file (see Fig. \[\]) named \texttt{hcp}. The constant \textit{i} is needed in the IDB file to initialize the first vertex in the graph. The command line argument would be:

\texttt{ground -r hcp -d 1.gph -c i=1}

The theory file produced would be named \texttt{1_1.gphhcp.tdc}.

The second module of the DC system, \texttt{dcs}, has as input the theory file produced by \texttt{ground}. A file named \texttt{dcs.stat} is created or appended with statistics concerning the results of executing \texttt{dcs} on the theory. The command line arguments are:

\texttt{dcs -f filename [-A] [-P] [-C] [-V]}

\textbf{Required arguments}

\texttt{-f filename} is the name of the file containing a theory produced by \texttt{ground}.

\textbf{Optional arguments}

\texttt{-A} Prints the positive atoms for solved theories in readable form.

\texttt{-P} Prints the input theory and then exits.

\texttt{-C} Counts the number of solutions. This information is recorded in the statistics file.

\texttt{-V} Prints information during execution (branching, backtracking, etc). Useful for debugging.

\textbf{Discussion of \texttt{dcs}}

The DC solver uses a Davis-Putnam type approach, with backtracking, propagation and LookAHead to deal with constraints represented as clauses, \texttt{select} constraints and Horn rules, and to search for answer sets. The LookAHead in DC is similar to local processing performed in \texttt{csat (DABC96)}. However, we use different methods to determine how many literals to consider in the LookAHead phase. Other techniques, especially propagation and search heuristics, were designed specifically for the case of DC as they must take into account the presence of Horn rules in programs.

Propagation consists of methods to reduce the theory. Literals which appear in the heads of Horn rules, \(l_h \in \text{At}_H\) require different interpretations. A literal is a \(l_h\) if and only if it appears in the head of a Horn rule. We can not guess an assignment for \(l_h\) rather it must be computed. We can only assign value true to \(l_h\) if it appears in the head of a Horn rule for which all literals in the body of the Horn rule have been assigned the value true. If one or more literals in the body of a Horn rule have been assigned the value false then that rule is removed. If \(l_h\) has not been assigned a value and all Horn rules in which \(l_h\) appeared in the head have been removed then \(l_h\) is assigned the value false. If we have a post-constant that required a value be assigned to \(l_h\) and the value cannot be computed then we must backtrack.

Non Horn rules are constraints which must be satisfied. These rules are identified by tags which indicate which method is needed to evaluate the constraint during propagation.

The LookAHead procedure tests a number of literals not yet assigned a value. The LookAHead procedure is similar to the local processing procedure used for \texttt{csat (DABC96)}. A literal is chosen, assigned the value true, then false using propagation to reduce and evaluate the resulting theories. If both evaluations of assignments result in conflicts then we return false and backtracking will result. If only one evaluation results in conflict then we can assign the literal the opposite value and continue the LookAHead procedure. If neither evaluation results in conflict we cannot make any assignments, but we save information (number of forced literals and satisfied constraints) computed during the evaluations of the literal.

The number of literals to be tested has been determined empirically. It is obvious that if all unassigned literals were tested during each LookAHead it would greatly increase the time. However, if only a small number of literals are to be tested during each LookAHead then they must be chosen to provide the best chance of reducing the theory. To choose the literals with the best chance of reducing the theory, we order the unassigned literals based on a sum computed by totaling the weights of the unsatisfied constraints in which they appear. The constraint weight is based on both the length and type of constraint. The shorter the constraint the larger the weight and when literals are removed the weight is recomputed. The literals are tested in descending order of the sum of constraints weights. Using this method we need to test only a very small number of literals during each LookAHead to obtain good results.

At the completion of the LookAHead procedure, we use the information computed during the evaluation of literals to choose the next branching literal and its initial truth assignment.

\textbf{Expressivity}

The expressive power of DC is the same as that of logic programming with the stable-model semantics. The following theorem is presented in \cite{ET00}.

\textbf{Theorem 1} \textit{The expressive power of DC is the same as that of stable logic programming. In particular, a decision problem II can be solved uniformly in DC if and only if II is in the class NP.}
The DC system provides a language, $L_{dc}$, which facilitates writing problem descriptions. Once an IDB is written in $L_{dc}$ it can be used for any instance of the problem for which data, in the EDB format, is available or can be generated. It is possible to add constraints to IDB for a given problem when new requirements or constraints occur. The constructs used in $L_{dc}$ allow for a natural description of constraints. Users need only know enough about a specific problem to be able to describe the problem in $L_{dc}$ (there is a user’s manual with examples). To help with programming in DC ground provides error messages and compiling information that are useful for debugging the IDB.

Benchmarks
The DC system has been executed using problems from NP, combinatorics, and planning. In particular, it has been used to compute hamilton cycles and colorings in graphs, to solve the N-queens problem, to prove that the pigeonhole problem has no solution if the number of pigeons exceeds the number of holes, and to compute Schur numbers.

The instances for computing hamilton cycles were obtained by randomly generating one thousand directed graphs with $v = 30, 40 \ldots, 80$ and density such that $\approx 50\%$ of the graphs contained hamilton cycles.

The graphs for instances of coloring were one hundred randomly generated graphs for $v = 50, 100, \ldots, 300$ with density such that $\approx 50\%$ had solutions when encode as 3-coloring.

Table 1: Schur problem; times

| B-N | csat | dcs | smodel |
|-----|------|-----|--------|
|     | sec  | sec | sec    |
| 3-13| 0.03 | 0.00| 0.12   |
| 3-14| 0.05 | 0.00| 0.16   |
| 4-14| 0.05 | 0.01| 0.23   |
| 4-43| 0.59 | 1.91| 5.23   |
| 4-44| 1.95 | 51.04| 5.55  |
| 4-45| 1599.92| 226.44| 12501.00 |

Figure 3: Results of computing hamilton cycles; log scale

Figure 4: Results on encodings of coloring problems; log scale

Figure 5: N-queens problem; log scale

Comparison
We have used the benchmarks to compare DC with systems based on stable model semantics and satisfiability. The performance of DC solver dcs was compared with smodels, a system for computing stable models of logic programs [NS96], and csat, a system for testing propositional satisfiability [DABC96]. In the case of smodels we used version 2.24 in conjunction with the grounder lparse, version 0.99.41 [Nie98]. The extended rules [Sim99] allowed in the newer versions of smodels and lparse were used where applicable. The programs were all executed on a Sun SPARC Station 20. For each test we report the cpu user times for processing the corresponding propositional program or theory. We tested all three system using the benchmarks discussed in the previous section.

Note that csat performs comparable to DC for pigeonhole (see Fig. 6), N-queens (see Fig. 5) and coloring (see Fig. 4). These are problems where DC en-

Table 2: Difference in size of theories for hamilton cycle
Experimental results show that dcs often outperforms systems based on satisfiability as well as systems based on non-monotonic logics, and that it constitutes a viable approach to solving problems in AI, constraint satisfaction and combinatorial optimization. We believe that our focus on short encodings (see Fig. 2) is the key to the success of dcs.
