Abstract

We suggest a generalization of the Lie algebraic approach for constructing quasi-exactly solvable one-dimensional Schrödinger equations which is due to Shifman and Turbiner in order to include into consideration matrix models. This generalization is based on representations of Lie algebras by first-order matrix differential operators. We have classified inequivalent representations of the Lie algebras of the dimension up to three by first-order matrix differential operators in one variable. Next we describe invariant finite-dimensional subspaces of the representation spaces of the one-, two-dimensional Lie algebras and of the algebra \( sl(2,\mathbb{R}) \). These results enable constructing multi-parameter families of first- and second-order quasi-exactly solvable models. In particular, we have obtained two classes of quasi-exactly solvable matrix Schrödinger equations.

1. Introduction

There exists a small number of remarkable Hamiltonians (called exactly-solvable) whose spectra and corresponding eigenfunctions can be computed

*e-mail: rzhdanov@apmat.freenet.kiev.ua
in a purely algebraic way (see, e.g. [1]). However, the choice of such Hamiltonians is too restricted to meet numerous requirements coming from different fields of modern quantum physics. Recently, an intermediate class of Hamiltonians was introduced by Turbiner [2] and Ushveridze [3] which allow an algebraic characterization of the part of their spectra. They call spectral problems of this kind quasi-exactly solvable.

Quasi-exactly solvable models have an amazingly wide range of applications in different fields of theoretical physics including conformal quantum field theories [4], solid-state physics [5] and Gaudin algebras (an excellent survey on this subject and an extensive list of references can be found in the monograph by Ushveridze [6]). So it was only natural that there appeared different approaches to constructing quasi-exactly solvable models, including the one based on their conditional symmetries (for more details, see [7]). However, for the purposes of this paper the most appropriate is the Lie-algebraic approach suggested by Shifman and Turbiner [8, 9] and further developed by González-López, Kamran and Olver [10]–[12]. That is why we will give its brief description (further details can be found in [6]).

The Lie-algebraic approach to constructing quasi-exactly solvable one-dimensional stationary Schrödinger equations

\[
\left(-\frac{d^2}{dx^2} + V(x)\right)\psi(x) = \lambda\psi(x)
\]

(1)

relies heavily upon the properties of representations of the algebra \(sl(2, \mathbb{R})\)

\[
\begin{align*}
\{Q_0, Q_\pm\} &= \pm Q_\pm, & \{Q_-, Q_+\} &= 2Q_0
\end{align*}
\]

by first-order differential operators. Namely, the approach in question utilizes the fact that the representation space of the algebra \(sl(2, \mathbb{R})\) having the basis elements

\[
Q_- = \frac{d}{dx}, \quad Q_0 = x\frac{d}{dx} - \frac{n}{2}, \quad Q_+ = x^2\frac{d}{dx} - nx,
\]

(2)

where \(n\) is an arbitrary natural number, has an \((n + 1)\)-dimensional invariant subspace. Its basis is formed by the polynomials in \(x\) of the order not higher than \(n\). Due to this fact, any bilinear combination of the operators (2) with constant coefficients yields a quasi-exactly solvable Hamiltonian \(\mathcal{H}\) such that the equation \(\mathcal{H}\psi = \lambda\psi\) can always be reduced to the form (1) with the help of a transformation

\[
\psi(x) \rightarrow F(x)\tilde{\psi}(f(x)).
\]
Note that the above described procedure does not guarantee that eigen-functions of thus constructed quasi-exactly solvable Hamiltonians will be square-integrable. What can be done within this approach is to reduce a ‘differential’ eigenvalue problem to a matrix one. The matter of a square integrability as well as other analytical properties of solutions obtained are to be investigated separately by independent methods (see, e.g. [13]).

Recently, a number of papers devoted to constructing matrix quasi-exactly solvable models has been published [14]–[17]. These papers use the same basic idea which is to fix a concrete subspace of sufficiently smooth multi-component functions and then to classify all second-order matrix differential operators leaving this subspace invariant. Furthermore, the above subspace is chosen to be the space of all multi-component functions with polynomial components. Posed in this way, the problem of constructing matrix quasi-exactly solvable includes as a subproblem a one of classifying realizations of Lie superalgebras by differential operators. Being very rich in interesting and important results this approach, however, contains an evident restriction which does not allow constructing all possible quasi-exactly solvable models. What we mean is the fact that an invariant subspace to be found is not necessarily formed by functions having polynomial coefficients. It is one of the results of the present paper that there exist principally different invariant subspaces. Thus there is a necessity for developing alternative approaches to the problem in question that do not require fixing a priori an invariant subspace.

Our initial motivation for studying matrix quasi-exactly solvable problems was to extend the list of exactly solvable Dirac equations of an electron via separation of variables. To this end we have suggested in [18] a method for constructing matrix quasi-exactly solvable models based on a direct generalization of the Lie-algebraic approach for the case of multi-component wave functions. However, it turns out that the above method is universal enough to be applied for obtaining second-order quasi-exactly solvable models as well, including the Schrödinger equations with matrix potentials.

Following [18] we extend the class to which should belong basis elements of a Lie algebra under study (say, of the algebra sl(2, R)). We define this class as the set of matrix differential operators

$$Q = \xi(x) \frac{d}{dx} + \eta(x),$$  \hspace{1cm} (3)
where $\xi(x)$ is a smooth real-valued function, $\eta(x)$ is a smooth complex-valued $r \times r$ matrix function, and denote it as $\mathcal{M}$. The class $\mathcal{M}$ is closed with respect to the binary operation

$$\{Q_1, Q_2\} \rightarrow Q_1 Q_2 - Q_2 Q_1 \overset{\text{def}}{=} [Q_1, Q_2]$$

and, consequently, form the infinite-dimensional Lie algebra.

We will classify inequivalent representations of low dimension ($d \leq 3$) Lie algebras by operators belonging to $\mathcal{M}$. Next, we will study the additional constraints on the form of basis operators of the one- and two-dimensional Lie algebras imposed by the requirement that their representation spaces contain finite-dimensional invariant subspaces. These results will be used to obtain an exhaustive description of inequivalent representations of the algebra $sl(2, \mathbb{R})$ by matrix differential operators (3) with $r = 2$. Composing linear and bilinear combinations of basis elements of $sl(2, \mathbb{R})$ with constant matrix coefficients will yield multi-parameter first- and second-order quasi-exactly solvable matrix models.

2. Classification of representations of low dimension Lie algebras

Since our aim is to get a quasi-exactly solvable model, we have to impose an additional restriction on the choice of the basis elements of the Lie algebras to be considered below. Namely, it is supposed that there exists at least one basis element such that the coefficient of $\frac{d}{dx}$ does not vanish identically. This constraint is required to avoid purely matrix representations which are useless in context of quasi-exactly solvable models.

Consider a first-order differential operator $Q = \xi(x) \partial_x + \eta(x)$ with $\xi \neq 0$. Note that hereafter we denote $\frac{d}{dx}$ as $\partial_x$. Let the function $f(x)$ be defined by the relation

$$f(x) = \int_a^x \frac{dy}{\xi(y)}, \quad a \in \mathbb{R}$$

and the matrix $r \times r$ function $F(x)$ be a solution of system of ordinary differential equations

$$\xi(x) \frac{dF(x)}{dx} + \eta(x) F(x) = 0$$
with \( \det F(x) \neq 0 \). Then the equivalence transformation

\[
Q \rightarrow \tilde{Q} = (F(x))^{-1} Q F(x)
\]

with a subsequent change of the dependent variable

\[
\tilde{x} = f(x)
\]

reduce the operator \( Q \) to become \( \tilde{Q} = \partial_{\tilde{x}} \). Consequently, any one-dimensional Lie algebra of first-order matrix differential operators \( Q = \xi(x)\partial_x + \eta(x) \) with \( \xi \neq 0 \) is equivalent to the algebra \( \langle \partial_x \rangle \).

Abstract Lie algebras of dimension up to five have been classified by Mubarakzyanov in \([19]\). Below we give the lists of (non-zero) commutation relations which determine inequivalent Lie algebras of the dimension up to three. Note that the algebras which are direct sums of lower dimension Lie algebras are skipped from the lists.

\[
\begin{align*}
L_{2,1} & : [Q_1, Q_2] = Q_1; \\
L_{3,1} & : [Q_2, Q_3] = Q_1; \\
L_{3,2} & : [Q_1, Q_3] = Q_1, \quad [Q_2, Q_3] = Q_1 + Q_2; \\
L_{3,3} & : [Q_1, Q_3] = Q_1, \quad [Q_2, Q_3] = Q_2; \\
L_{3,4} & : [Q_1, Q_3] = Q_1, \quad [Q_2, Q_3] = -Q_2; \\
L_{3,5} & : [Q_1, Q_3] = Q_1, \quad [Q_2, Q_3] = aQ_2, \quad (0 < |a| < 1); \\
L_{3,6} & : [Q_1, Q_3] = -Q_2, \quad [Q_2, Q_3] = Q_1; \\
L_{3,7} & : [Q_1, Q_3] = aQ_1 - Q_2, \quad [Q_2, Q_3] = Q_1 + aQ_2, \quad (a > 0); \\
L_{3,8} & : [Q_1, Q_2] = Q_1, \quad [Q_1, Q_3] = 2Q_2, \quad [Q_2, Q_3] = Q_3; \\
L_{3,9} & : [Q_1, Q_2] = Q_3, \quad [Q_2, Q_3] = Q_2, \quad [Q_3, Q_1] = Q_2.
\end{align*}
\]

Here \( a \) is a real parameter, the symbol \( L_{n,m} \) stands for a Lie algebra of the dimension \( n \) numbered by \( m \).

Thus there exists only one two-dimensional Lie algebra \( L_{2,1} = \langle Q_1, Q_2 \rangle \) which is not a direct sum of one-dimensional Lie algebras.

If in operator \( Q_1 = \xi(x)\partial_x + \eta(x) \) the coefficient \( \xi \) is not identically zero, then using equivalence transformations defined at the beginning of this section we can reduce it to the form \( Q_1 = \partial_{\tilde{x}} \). Inserting \( Q_1 = \partial_{\tilde{x}}, Q_2 = \xi(\tilde{x})\partial_{\tilde{x}} + \tilde{\eta}(\tilde{x}) \) into the commutation relation \([Q_1, Q_2] = Q_1\) and equating
the coefficients of the powers of the operator $\partial_{\tilde{x}}$ yield system of ordinary differential equations for $\tilde{\xi}(\tilde{x})$, $\tilde{\eta}(\tilde{x})$

$$\frac{d\tilde{\xi}}{d\tilde{x}} = 1, \quad \frac{d\tilde{\eta}}{d\tilde{x}} = 0.$$  

Hence we obtain $\tilde{\xi} = \tilde{x} + C_1$, $\tilde{\eta} = A$, where $C_1 \in \mathbb{R}$ is an arbitrary constant and $A$ is an arbitrary constant $r \times r$ matrix. Shifting when necessary the variable $\tilde{x}$ by a constant $C_1$ we may put $C_1 = 0$ and thus get $Q_2 = \tilde{x} \partial_{\tilde{x}} + A$.

If the operator $Q_1$ has the form $\eta(x)$, then by convention the coefficient of $\partial_x$ of the operator $Q_2$ does not vanish identically. Consequently, there exists an equivalence transformation reducing the latter to the form $Q_2 = \partial_{\tilde{x}}$. Substituting $Q_1 = \tilde{\eta}(\tilde{x})$, $Q_2 = \partial_{\tilde{x}}$ into the commutation relation of the algebra $L_{2,1}$ and equating the coefficients of the powers of the operator $\partial_{\tilde{x}}$ we obtain the following equations for $\tilde{\eta}(\tilde{x})$:

$$\frac{d\tilde{\eta}}{d\tilde{x}} = -\tilde{\eta},$$

whence

$$\tilde{\eta}(\tilde{x}) = Ae^{-\tilde{x}}.$$  

Here $A$ is an arbitrary $r \times r$ constant matrix.

Summing up, we conclude that the two realizations of the algebra $L_{2,1}$

(1) $Q_1 = Ae^{-x}$, $Q_2 = \partial_x$;

(2) $Q_1 = \partial_x$, $Q_2 = x\partial_x + A$

exhaust the set of all possible inequivalent representations of the algebra in question within the class of matrix differential operators $\mathcal{M}$.

In a similar way we have obtained complete lists of inequivalent representations of the three- and four-dimensional Lie algebras within the class $\mathcal{M}$ which are given below.

$L_{3,1}$: $Q_1 = A$, $Q_2 = \partial_x$, $Q_3 = \epsilon \partial_x + Ax + B$,

$[A, B] = 0$;

$L_{3,2}$: $Q_1 = Ae^{-x}$, $Q_2 = \epsilon e^{-x} \partial_x + (B - Ax)e^{-x}$, $Q_3 = \partial_x$,

$[A, B] = -\epsilon A$;
In the above formulae $\alpha$ is an arbitrary constant, $\epsilon = 0, 1$, and $A, B$ are $r \times r$ constant matrices.

3. Quasi-exactly solvable matrix models

As a second step of an implementation of the Lie-algebraic approach to constructing matrix quasi-exactly solvable models we have to pick out from the whole set of realizations of Lie algebras listed in the previous section those
having finite-dimensional invariant subspaces.

Consider first the one-dimensional Lie algebra $\langle \partial_x \rangle$. A space with basis vectors $f_1(x), \ldots, f_n(x)$ is invariant with respect to the action of the operator $\partial_x$ if there exist complex constants $\Lambda_{ij}$ such that

$$\frac{df_i(x)}{dx} = \sum_{j=1}^{n} \Lambda_{ij} f_j(x)$$

for all $i = 1, \ldots, n$. Solving this system of ordinary differential equations yields the following expressions for unknown vector-functions $f_i$:

$$f_i(x) = \sum_{j=1}^{r} \sum_{k=1}^{n} (e^{\Lambda x})_{ik} C_{kj} e_j,$$

where $\Lambda$ is the constant $n \times n$ matrix having the entries $\Lambda_{ij}$; $C_{kj}$ are arbitrary complex constants; the symbol $(A)_{ij}$ stands for the $(i, j)$th entry of the matrix $A$ and $e_1, \ldots, e_r$ are constant vectors forming an orthonormal basis of the space $\mathbb{R}^r$.

It follows from the general theory of matrices that the above formulae can be represented in the following equivalent form (see, e.g. [20]):

$$f_i(x) = \sum_{j=1}^{m} e^{\alpha_j x} \sum_{k=1}^{n} P_{ijk}^{[n-m]}(x) e_k.$$ (6)

Here $\alpha_1, \ldots, \alpha_m$ are arbitrary complex numbers with $|\alpha_i| < |\alpha_{i+1}|$, the symbol $P_{ijk}^{[n-m]}(x)$ stands for an $(n - m)$th degree polynomial in $x$, $1 \leq m \leq n$, $k = 1, \ldots, n$.

As each realization of the low dimension Lie algebras obtained in Sec.II contains the operator $\partial_x$, their finite-dimensional invariant subspaces are necessarily of the form (5). In what follows we will obtain complete description of finite-dimensional invariant subspaces of the representation spaces of the representations of the two-dimensional Lie algebra $L_{2,1}$ given in Proposition 3.

First we turn to the case (4). Let us study the restrictions on the choice of the basis vector-functions (6) imposed by a requirement that the corresponding vector space $V_n$ is invariant with respect to the action of the operator $Q_2 = Ae^{-x}$. By assumption, there exist complex constants $S_{ij}$ such that the relations

$$Ae^{-x} f_i = \sum_{j=1}^{n} S_{ij} f_j$$
hold with $i = 1, \ldots, n$. Hence we get

$$\sum_{j=1}^{m} e^{(\alpha_j-1)x} \sum_{k=1}^{r} P_{ijk}^{[n-m]}(x)Ae_k = \sum_{j=1}^{m} e^{\alpha_j x} \sum_{k=1}^{r} \tilde{P}_{ijk}^{[n-m]}(x)e_k,$$

where

$$\tilde{P}_{ijk}^{[n-m]} = \sum_{l=1}^{n} S_{il} P_{ijk}^{[n-m]}.$$

Comparing the coefficients of $e^{\alpha_i x}$ yield that $\alpha_{i+1} = \alpha_i + 1$, $i = 1, \ldots, m - 1$ and furthermore

$$\sum_{k=1}^{r} P_{i1k}^{[n-m]}(x)Ae_k = 0 \quad (7)$$

for all $i = 1, \ldots, n$.

Let us choose the new basis of the space $\mathbb{R}^r$ in such a way that the first $s$ basis elements $e_1, \ldots, e_s$ are eigenvectors of the matrix $A$ with zero eigenvalues, namely

$$Ae_i = 0, \quad i = 1, \ldots, s.$$

Given this choice of the basis, it follows from (7) that $P_{i1k}^{[n-m]}(x) = 0$, $k = s + 1, \ldots, r$. Hence, we conclude that the remaining basis vectors $e_{s+1}, \ldots, e_r$ satisfy the relations

$$Ae_i = \sum_{j=1}^{s} a_{ij} e_j, \quad i = s + 1, \ldots, r$$

with some constant $a_{ij}$.

Thus, the most general $n$-dimensional vector space $V_n$ invariant with respect to the Lie algebra $\langle \partial_x, Ae^{-x} \rangle$ is spanned by the vectors

$$f_i(x) = e^{\alpha x} \sum_{j=2}^{m} e^{(j-1)x} \sum_{k=1}^{r} P_{ijk}^{[n-m]}(x)e_k + e^{\alpha x} \sum_{j=1}^{s} P_{ij}^{[n-m]}(x)e_j,$$

where $\alpha$ is an arbitrary complex constant, $P_{ijk}^{[n-N]}(x)$, $P_{ij}^{[n-N]}(x)$ are arbitrary $(n-N)$th order polynomials in $x$, $i = 1, \ldots, n$. And what is more the matrix $A$ is of the following form:

$$A = \begin{pmatrix} 0 & \tilde{A} \\ 0 & 0 \end{pmatrix},$$

9
where $\tilde{A}$ is an arbitrary constant $s \times (r - s)$ matrix.

Now we turn to the representation (5). It is necessary to investigate the restrictions on the choice of the basis vector-functions (5) imposed by a requirement that the corresponding vector space $V_n$ is invariant with respect to the action of the operator $Q_2 = x\partial_x + A$. By assumption, there exist complex constants $S_{ij}$ such that the relations

$$\left(x\frac{d}{dx} + A\right)f_i = \sum_{j=1}^{n} S_{ij} f_j$$

hold with $i = 1, \ldots, n$. Inserting the expressions (5) into these equations and comparing the coefficients of $e^{\alpha_j x} x^k$ we arrive at the conclusion that $\alpha_1 = \cdots = \alpha_m = 0$. With this restriction the formulae (5) give the most general finite-dimensional invariant subspace of the representation space of the Lie algebra $\langle \partial_x, x\partial_x + A \rangle$

$$f_i(x) = \sum_{k=1}^{r} P_{i k}^{[n-1]}(x) e_k, \quad i = 1, \ldots, n.$$ 

A detailed investigation of finite-dimensional invariant subspaces admitted by the three- and four-dimensional Lie algebras is in progress now and will be the topic of our future publications.

In what follows we will construct examples of quasi-exactly solvable two-component matrix models based on representations of the Lie algebra $L_{3,8} = \mathfrak{sl}(2, \mathbb{R})$. The construction procedure rely upon the assertion below which is given without proof.

**Theorem 1** The representation space of the algebra sl$(2, \mathbb{R})$ having the basis elements

$$Q_1 = \partial_x, \quad Q_2 = x\partial_x + A, \quad Q_2 = x^2\partial_x + 2xA + B,$$  

where $A, B$ are constant $2 \times 2$ matrices satisfying the relation $[A, B] = B$, contains a finite dimensional invariant subspace iff the matrices $A, B$ are of the form

1) $A = \begin{pmatrix} -\frac{n}{2} & 0 \\ 0 & -\frac{m}{2} \end{pmatrix}, \quad B = \begin{pmatrix} 0 & 0 \\ 0 & 0 \end{pmatrix}$, or  

2) $A = \begin{pmatrix} -\frac{n}{2} & 0 \\ 0 & 2-n \end{pmatrix}, \quad B = \begin{pmatrix} 0 & 0 \\ -1 & 0 \end{pmatrix}$.  

10
Here \( n, m \) are arbitrary natural numbers with \( n \geq m \).

Using the fact that the algebra in question has the Casimir operator \( C = B \partial_x + A - A^2 \) it is not difficult to become convinced of the fact that representations of the form (8), (9) are the direct sums of two irreducible representations realized on the representation spaces

\[
\mathcal{R}_1 = \langle \vec{e}_1, x \vec{e}_1, \ldots, x^n \vec{e}_1 \rangle, \quad \mathcal{R}_2 = \langle \vec{e}_2, x \vec{e}_2, \ldots, x^m \vec{e}_2 \rangle,
\]

where \( \vec{e}_1 = (1, 0)^T, \vec{e}_2 = (0, 1)^T \).

Representations (8), (10) are also the direct sums of two irreducible representations realized on the representation spaces

\[
\mathcal{R}_1 = \langle n\vec{e}_1, \ldots, nx^j \vec{e}_1 + jx^{j-1} \vec{e}_2, \ldots, nx^n \vec{e}_1 + nx^{n-1} \vec{e}_2 \rangle, \\
\mathcal{R}_2 = \langle \vec{e}_2, x \vec{e}_2, \ldots, x^{n-2} \vec{e}_2 \rangle.
\]

According to the scheme given in the Introduction to get a quasi-exactly solvable model we have to compose a linear combination of basis elements of a Lie algebra of differential operators whose representation space has finite dimensional invariant subspace \( V_n \). And what is more, coefficients of this linear combination are constant matrices of the corresponding dimension whose action leaves the space \( V_n \) invariant.

Consider first the representation (8), (9) with \( n = m \). According to the above its representation space contains \( 2(n + 1) \)-dimensional invariant subspace \( V_{2n+2} \) spanned by the vectors \( \vec{e}_1 x^j, \vec{e}_2 x^j, j = 0, \ldots, n \). A direct verification shows that \( V_{2n+2} \) is invariant with respect to action of any \( 2 \times 2 \) matrix. Composing a linear combination of (8), (9) under \( n = m \) with coefficients being arbitrary \( 2 \times 2 \) matrices yields the following quasi-exactly solvable model:

\[
(A_1 + A_2x + A_3x^2) \frac{du(x)}{dx} + (A_4 - nx A_3) u = \lambda u.
\]

Here \( A_1, A_2, A_3, A_4 \) are arbitrary constant \( 2 \times 2 \) matrices, \( u(x) \) is a two-component vector-function.

Provided \( n = m + 1 \), the representation (8), (9) gives rise to a quasi-exactly solvable matrix model of the form

\[
(A_1 + B_1x + B_2x^2) \frac{du(x)}{dx} + (B_3 + B_2A) u = \lambda u,
\]

(12)
where $A_1$ is an arbitrary $2 \times 2$ matrix and $B_1, B_2, B_2$ are arbitrary upper triangular $2 \times 2$ matrices.

At last, if $n > m+1$, then the representation (8), (9) yields a quasi-exactly solvable matrix model of the form (12), where both $A_1$ and $B_1, B_2, B_3$ are arbitrary upper triangular $2 \times 2$ matrices.

A similar analysis shows that the representation (8), (10) gives rise to a quasi-exactly solvable model

$$
(B_1 + B_2 x + B_3 x^2)\frac{du(x)}{dx} + (B_4 + B_3 (2xA + B))u = \lambda u,
$$

where

$$B_i = \begin{pmatrix} \lambda_i & b_i \\ 0 & \lambda_i \end{pmatrix}, \quad i = 1, \ldots, 4$$

$\lambda_i, b_i$ being arbitrary complex constants.

Needless to say that any linear matrix model obtained from one of the above quasi-exactly solvable models by a change of variables is in its turn quasi-exactly solvable. In other words, equations (11)–(13) are representatives of equivalence classes of quasi-exactly solvable models. Other representatives are obtained via transformation of variables

$$x \rightarrow \tilde{x} = f(x), \quad u \rightarrow F(x)\tilde{u},$$

where $f(x)$ is a smooth function and $F(x)$ is an arbitrary invertible $2 \times 2$ matrix whose entries are smooth functions of $x$.

In the same way second-order quasi-exactly solvable matrix models are constructed. In particular, taking a bilinear combination of the operators (8) with $A, B$ being given either by (9) or by (10)

$$\mathcal{H} = \sum_{i,j=1, i \leq j}^3 \alpha_{ij} Q_i Q_j + \sum_{i=1}^3 \alpha_i Q_i,$$

where $\alpha_{ij}, \alpha_i$ are arbitrary real constants, yields two families of quasi-exactly solvable matrix models of the form

$$\mathcal{H}u = \lambda u.$$

By a suitable transformation (14) the latter can be transformed to become a matrix Schrödinger equation

$$\left(-\frac{d^2}{d\tilde{x}^2} + V(\tilde{x}) \right) \tilde{u} = \lambda \tilde{u}.$$
Here $V(\tilde{x})$ is the $2 \times 2$ matrix potential, whose explicit form depends essentially on the parameters $\alpha_{ij}, \alpha_i$ and on the integers $n, m$. Let us stress that the matter of hermiticity of thus obtained matrix potential is by no means clear and needs special investigation.

With a particular choice of the matrices $A, B$

$$A = \begin{pmatrix} -\frac{n}{2} & 0 \\ 0 & -\frac{n}{2} \end{pmatrix}, \quad B = \begin{pmatrix} 0 & 0 \\ 0 & 0 \end{pmatrix}$$

the well-known nine-parameter family of scalar quasi-exactly solvable Schrödinger equations is obtained \cite{2}–\cite{6}.

4. Conclusions

The present paper is aimed primarily at solving the problem of classification of quasi-exactly matrix models by purely algebraic means. As a result, we get some classes of systems of first- and second-order ordinary differential equations such that a problem of finding their particular solutions reduces to solving matrix eigenvalue problem. Now to decide whether a given specific matrix model is solvable within the framework of an approach expounded above, one has to check whether it is possible to reduce it with the help of a transformation \cite{14} to one of the canonical forms given in Sec.III. When one deals with a scalar model this check is being done trivially (see, for details, \cite{3}). However for the case of matrix models it involves tedious and cumbersome calculations and is by itself rather nontrivial algebraic problem. As an illustration we will adduce an instructive example. Consider the following two-component matrix model:

$$\mathcal{H} \mathbf{u} \equiv (ib\sigma_1 Q_1 + ia\sigma_2 Q_2 + c_1\sigma_1 + c_2\sigma_2) \mathbf{u} = \lambda \mathbf{u},$$

(15)

where $a, b, c_1, c_2$ are arbitrary real parameters with $ab \neq 0$, and $\sigma_1, \sigma_2$ are $2 \times 2$ Pauli matrices, and

$$Q_1 = \partial_x, \quad Q_2 = x\partial_x + \begin{pmatrix} 1 & 0 \\ 0 & 1 \end{pmatrix}.$$

This model is quasi-exactly solvable by construction. Making the change of variables

$$x = b \frac{a}{a} \sinh(ay),$$

13
\[
\vec{w}(x) = (\cosh(ay))^{1/2} \exp \left\{ -\frac{i}{a} \left( c_1 \arctan \sinh(ay) + c_2 \ln \cosh(ay) \right) \right\} \\
\times \exp \{ -i\sigma_3 \arctan \sinh(ay) \} \vec{\psi}(y)
\]

we reduce (15) to the Dirac-type equation

\[
i\sigma_1 \frac{d\vec{\psi}}{dy} + \sigma_2 V(y) \vec{\psi}(y) = \lambda \vec{\psi},
\]

where

\[
V(y) = \frac{a^2c_2 - b^2c_1 \sinh(ay)}{ab \cosh(ay)}
\]
is the well-known hyperbolic Pöschl-Teller potential. This means that the Dirac equation (14) with the hyperbolic Pöschl-Teller potential is quasi-exactly solvable.

Thus an application of the obtained results to decide whether a given model is quasi-exactly solvable requires a considerable experience in manipulating matrix exponents. Generically, to check which equations of the form (16) can be reduced to one of the quasi-exactly solvable models constructed at the end of the previous section one has to solve systems of nonlinear algebraic equations.

A technique used in the present paper can be generalized in order to enable one to classify multi-dimensional matrix models in a way as it was done for a scalar case by González-López, Kamran and Olver [10]–[12].

The last important remark is that the property of quasi-exact solvability is intimately connected to the conditional symmetry of a model under study. This fact was for the first time noticed in our paper [7], where we proved that quasi-exact solvability of stationary Schrödinger equations is in one-to-one correspondence with their conditional symmetry. As we believe, similar results can be obtained for matrix quasi-exactly solvable models as well.
